IgG/γ	Monomer/2	13.5/70–80%	Major circulating antibody; four sub-classes: IgG1, IgG2, IgG3, IgG4; IgG1 and IgG3 activate complement	Extracellular fluid; blood and lymph; intestine; crosses placenta
IgM/μ	Pentamer/10 Monomer/2	1.5/6–10% 0	First antibody to appear in primary response to extracellular pathogens or after immunization; pentamer especially effective in agglutinating antigens; strong complement activator	Blood and lymph; monomer is B cell surface receptor (BCR)
IgA/α	Monomer/2	3.5/10–20%	Important circulating antibody	Monomer conformation is present in blood and lymph; dimer conformation is present in secretions, such as mucus, saliva, and breastmilk colostrum
	Dimer/4	0.05/0.2–0.3%	Major secretory antibody	
IgD/δ	Monomer/2	0.03/0.2–0.3%	Minor circulating antibody; mostly associated with mature B cells	B cell surface receptor (BCR); blood and lymph (trace)
IgE/ε	Monomer/2	0.00005/0.0003%	Facilitates parasite immunity but also triggers allergic reactions	Blood and lymph; binds to mast cells and eosinophils

^aAll immunoglobulins may have either λ or κ light-chain types, but not both.

chains) are paired with two identical longer chains of about 50 kDa (called *heavy chains*), yielding a Y-shaped, symmetrical molecule. Each heavy chain interacts with a light chain to form a functional *antigen-binding site*. Therefore, an IgG antibody molecule is *bivalent* because it has two identical sites that bind two identical antigenic determinants.

Heavy and light chains consist of variable and constant protein domains. A heavy-chain *variable domain* is connected to three heavy-chain *constant domains* (Figure 27.8a). The variable domain (V_H) and the first constant domain (C_{H1}) compose part of the *Fab* (fragment, antigen-binding) portion of the immunoglobulin, so named because it contains the antigen-binding site. The two constant domains located most distal to the variable domain (C_{H2} and C_{H3}) compose the *Fc* (fragment, crystalline) region of the antibody, named for its tendency to crystallize in solution. As previously

mentioned, it is the Fc region of the antibody that binds FcR molecules on the surface of phagocytes to facilitate phagocytosis. The light chains of the antibody consist of one variable (V_L) and one constant (C_L) domain each and contribute to the two Fab regions only (Figure 27.8a).

Because the variable domains of a given antibody bind a specific antigenic determinant, their amino acid sequences vary in each different antibody. The variable domain of a light chain (V_L) interacts with the variable domain of a heavy chain (V_H) to bind antigen. By contrast, the constant domains of each antibody are identical in amino acid sequence for all Ig molecules of a given class.

Other Immunoglobulin Classes and Their Functions

Immunoglobulins of the other classes differ from IgG in structure and function. Because the amino acid sequence of heavy-chain constant domains determines antibody class, the heavy chain called

gamma (γ) defines the IgG class. Likewise, *alpha* (α) defines IgA; *mu* (μ) defines IgM; *delta* (δ) defines IgD; and *epsilon* (ε) defines IgE (Table 27.2). The heavy chains of IgM and IgE contain four constant domains, whereas the heavy chains of IgG, IgA, and IgD contain only three (Figure 27.9a, b).

The monomeric and pentameric structures of IgM are shown in Figure 27.9b and c, respectively. Circulating IgM forms an aggregate of five or six immunoglobulin molecules attached by at least one J (joining) peptide (Figure 27.9c). Pentameric

Figure 27.8 Immunoglobulin G structure. (a) IgG consists of two heavy chains (50,000 molecular weight) and two light chains (25,000 molecular weight), with a total molecular weight of 150,000. One heavy and one light chain interact to form an antigen-binding unit. The variable domains of the heavy (V_H) and light chains (V_L) bind antigen. The constant domains (C_{H1}, C_{H2}, C_{H3}, C_L) are identical in all IgG proteins. The chains are covalently joined with disulfide bonds, shown here as connecting black lines. The Fab (fragment, antigen-binding) region contains the antigen-binding site. The Fc (fragment, crystalline) stem of the antibody binds receptor molecules on phagocytes to facilitate phagocytosis of opsonized pathogens. (b) Space-filling model of an IgG molecule. The heavy chains are red and dark blue. The light chains are green and light blue.

Figure 27.9 Immunoglobulin classes. All classes of Igs have V_H and V_L that bind antigen. (a) IgG, IgA, and IgD have three constant domains. (b) The heavy chains of IgM and IgE have a fourth constant domain. (c) IgM is found in serum as a pentameric protein consisting of five IgM proteins covalently linked to one another via disulfide bonds and a joining (J) chain protein. Because it is a bivalent pentamer, IgM can bind up to ten antigens, as shown. (d) Secretory IgA is often found in body secretions as a dimer consisting of two IgA proteins covalently linked to one another by a J chain protein. The secretory component aids in transport of IgA across mucosal membranes.

IgM is the first class of antibody produced in a typical immune response to a bacterial infection, but each individual antigen-binding site of an IgM pentamer generally has low *affinity* (binding strength) for antigen. However, the *avidity* (combined antigen-binding strength of multiple epitopes) of IgM antibodies is enhanced because each IgM

pentamer has ten binding sites available for interaction with antigen (Table 27.2 and Figure 27.9c). The ten antigen-binding sites make IgM especially effective at agglutinating (clumping) antigens, thereby increasing phagocytic efficiency. Like IgG, IgM is a strong activator of complement through the classical pathway. Whereas up to 10% of serum antibodies are pentameric IgM, IgM monomers do not circulate in the blood but rather are one of the classes of antibodies that function as BCRs.

Dimers of IgA are present in high numbers in secreted body fluids, including saliva, tears, breast milk colostrum, and mucosal secretions from the gastrointestinal, respiratory, and genitourinary tracts. The mucosal surfaces in an average adult, which total about 400 m² (skin has about 6 m²), contain MALT and produce large amounts (about 10 g) of secretory IgA every day. By comparison, an individual produces only about 5 g of serum IgG per day. Whereas *serum* IgA typically occurs in monomeric form (Table 27.2), *secretory* IgA consists of two IgA molecules covalently linked by a J chain peptide and complexed with a protein called the *secretory component* that aids in transport of IgA across membranes (Figure 27.9d). The high concentration of secretory IgA in breast milk colostrum likely plays a key role in preventing gastrointestinal disease in newborns.

Although IgE is present in small amounts in serum, most IgE is bound to cells. For example, through its Fc region IgE binds eosinophils, arming these granulocytes to target parasitic pathogens such as schistosomes and other helminths (► Section 34.7). IgE also binds to tissue mast cells, where subsequent binding of antigen to antigen-binding sites of IgE causes degranulation of the mast cells. The ensuing release of chemical mediators, such as histamine and serotonin, triggers immediate-type hypersensitivities (a type of allergic response; ► Section 28.1). Like IgM, IgE has a fourth heavy-chain constant domain (Figure 27.9b), and this allows for binding of IgE to eosinophils and mast cells, the key step for activating the protective and allergic reactions, respectively, associated with these cell types.

IgD (Figure 27.9a), present in serum in low concentrations, has no known unique immune protective function. However, IgD, like IgM, is abundant on the surfaces of mature B cells, especially memory B cells, where it functions as a BCR.

Antigen Exposure, Immune Memory, and the Primary and Secondary Responses

We have seen that immune memory is a major outcome of the adaptive immune response (Figure 27.1c). Starting with a B cell, an antibody-mediated immune response begins with antigen exposure and culminates with the production and secretion of antigen-specific antibodies, and the type and route of antigen exposure influences the class of the antibodies produced. Blood and lymph, as well as the spleen and MALT (Chapter 26), are key sites for engagement of antigens by immune components. Bloodborne pathogens/antigens are captured in the spleen, where IgM, IgG, and serum IgA antibodies are produced. Antigen introduced subcutaneously, intradermally, topically, or intraperitoneally is carried through the lymphatic system to the nearest lymph nodes, again stimulating production of IgM, IgG, and serum IgA. Antigen introduced to mucosal surfaces is delivered to the nearest MALT. For example, antigen delivered orally is delivered to the MALT in the intestinal tract, stimulating production of secretory IgA in the gut.

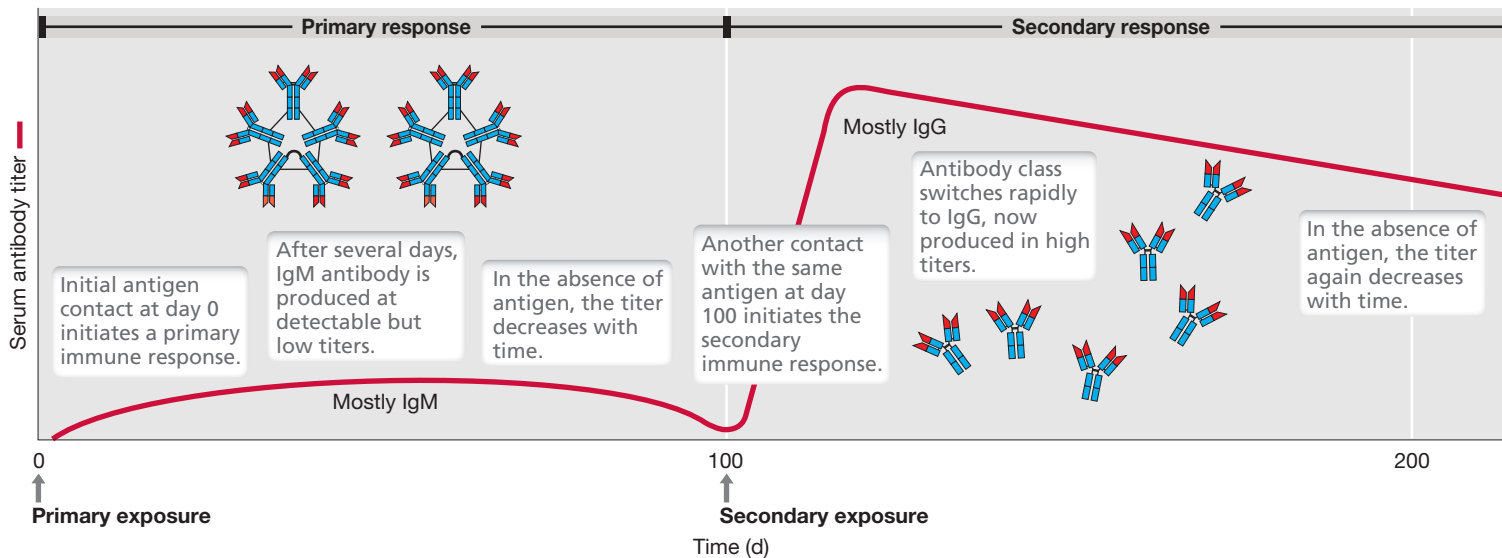

Figure 27.10 Primary and secondary antibody responses in serum. The antigen exposures at day 0 and day 100 must be to identical antigen to induce a secondary response. The secondary response, also called a booster response, may be more than 10-fold greater than the primary response. Note the class switch from IgM production in the primary response to IgG production in the secondary response.

Following initial BCR–antigen contact, each B cell stimulated by T-dependent antigen multiplies and differentiates to form antibody-secreting plasma cells and memory B cells (Figure 27.6). Plasma cells in this *primary antibody response* are relatively short-lived (less than one week) and secrete large amounts of mostly IgM antibody (Figure 27.10). After a latent period of several days, antibody appears in the blood and a gradual increase in *antibody titer* (antibody quantity) occurs. As antigen disappears, the primary antibody response slowly diminishes.

Memory B cells generated by the initial exposure to antigen may circulate in the host for years. A second exposure to the same antigen stimulates memory B cells to rapidly differentiate into plasma cells and produce antibody without input from helper T cells. The second and each subsequent exposure to antigen causes the antibody titer to rise rapidly to a level often 10–100 times greater than the titer following the first exposure (Figure 27.10). This rise in antibody titer is called the *secondary antibody response*. The secondary response is a function of immune memory and typically results in a switch from the production of IgM to another antibody class, a transition called *class switching* (Figure 27.10). This switch is induced by a cytokine signal produced in response to the specific type of pathogen. The signal prompts a recombination event that switches the heavy-chain constant region, resulting in the production of the antibody class that can most efficiently address the threat. For example, in serum, the most common antibody class switch is from IgM to IgG, whereas in mucosal tissues, switches to IgA predominate. It is important to note that class switching does not cause a change in antigen specificity; the new class of antibody generated remains specific to the original antigen.

Serum antibody titer slowly decreases over time, but subsequent exposure(s) to the same antigen can trigger another secondary response. This results in the maintenance of high levels of memory cells and circulating antibody specific for the antigen, providing long-term active immunity against individual infectious diseases.

27.4 Antigen Binding and the Genetics of Antibody Diversity

We have seen that antibodies consist of four polypeptides, two heavy (H) chains and two light (L) chains (Figure 27.8), and each chain is composed of constant (C) and variable (V) domains. The V domains of one H and one L chain interact to form the antigen-binding site. Here we examine the structural features of the V domains that define the antigen-binding site and then explore the genetics behind the enormous diversity of antibodies that, collectively, B cells are capable of producing.

Variable Domains and Antigen–Antibody Interaction

The V domains of an H and an L chain bind antigen strongly but not covalently. To accommodate all possible antigens that a host might encounter in a lifetime, the synthesis of billions of different antibodies, each with its own unique antigen-binding site, is necessary. The V domains define these unique antigen-binding sites.

Amino acid sequences differ in the V domains of Igs that bind different antigens. Amino acid variability is especially apparent in several **complementarity-determining regions (CDRs)**. Three CDRs in each of the V domains provide most of the molecular contacts with antigen (Figure 27.11). The amino acid sequences of CDR1 and CDR2 differ in minor ways between different Igs, while CDR3s differ dramatically in sequence from one another. Three distinct gene segments encode CDR3 of the H chain: the carboxy-terminal portion of

Figure 27.11 Antigen binding by immunoglobulin light and heavy chains. (a) An Ig is shown schematically, with bound antigen (light brown). The V domains on the H and L chains are shown in red (heavy chain) and pink (light chain) with their antigen-binding complementarity-determining regions (CDR1, CDR2, and CDR3). C_H1, C_H2, and C_H3 (dark blue) are constant domains in the H chain, and C_L (light blue) is the constant domain in the L chain. (b) CDRs from both H (red) and L (pink) chains, shown from above, are conformed to make a single antigen-binding site on the Ig. The highly variable CDR3s from both H and L chains cooperate at the center of the site. Antigen (light brown) may contact all CDRs. The shape of the site may be a shallow groove or a deep pocket, depending on the antibody–antigen pair involved.

the V domain, followed by a short “diversity” (D) segment of about three amino acids, and a longer “joining” (J) segment about 13–15 amino acids long. The light-chain CDR3 is similar except that it lacks the D segment. The heavy- and light-chain CDRs, six in total, confer antigen specificity on the antibody molecule (Figure 27.11).

The Ig three-dimensional structure was shown in Figure 27.8b. Each antigen–antibody interaction requires the specific binding of an antigenic *epitope* with the CDR domains of the H and L chains. A single antigen-binding site of an antibody molecule measures about 2 × 3 nm, creating a space large enough to accommodate an epitope of 10 to 15 amino acids. Antigen binding is ultimately a function of the Ig folding pattern of the H and L polypeptide chains. The Ig folds of the V region bring all six CDRs together, resulting in the formation of a unique and specific antigen-binding site (Figure 27.11).

Because antigen diversity is enormous, the immune system must be capable of producing antibodies to recognize a virtually unlimited variety of antigens. In order to accomplish this from a relatively small number of immunoglobulin genes, several unusual genetic mechanisms come into play. **Table 27.3** summarizes these diversity-generating mechanisms, and we explore each below.

Organization of Immunoglobulin Genes

The gene encoding each immunoglobulin H or L chain is constructed from several gene segments. In each B cell, Ig gene segments undergo a series of random, somatic rearrangements characterized by genetic recombination followed by deletion of intervening sequences. These events produce a single, functional antibody gene derived from a relatively small pool of Ig gene segments. As a B cell matures, V, D, and J gene segments are enzymatically recombined to form a single Ig heavy-chain gene (**Figure 27.12a**). The single V gene segment encodes CDR1 and CDR2, whereas CDR3 is encoded by a mosaic of the 3’ end of the V region, followed by the D and J gene segments.

In each B cell, only one productive Ig-encoding rearrangement each occurs in the heavy- and light-chain genes. Called *allelic exclusion*, this mechanism causes each B cell to express Ig genes from only one of the two inherited parental alleles, thus ensuring that all Igs from a given clone of B cells have identical antigen specificity. Finally, separate C gene segments encode the class-defining constant domains of Igs. Therefore, four different gene segments—V, D, J, and C—recombine to form one functional heavy-chain gene (Figure 27.12a). Light chains, which lack D segments, are encoded in a similar way by recombination of light-chain V, J, and C segments (Figure 27.12b). The gene segments required for all Igs exist in all nucleated cells of the body but undergo recombination only in developing B lymphocytes.

V, D, J, and C gene segments are separated by noncoding DNA sequences typical of gene arrangements in eukaryotes (◀ Section 6.6).

TABLE 27.3 Generation of antigen-binding receptor diversity in B cells and T cells		
Diversity-generating mechanism	B cell Ig receptors, heavy and light chains	T cell receptors, α and β chains
Somatic recombination of tandem genes	Yes	Yes
Random reassortment	Yes	Yes
Imprecise V-D-J or V-J joining	Yes	Yes
Nucleotide additions at V-D-J or V-J junctions	Yes	Yes
D gene segments read in all 3 frames	No	Yes
Somatic hypermutation	Yes	No

Figure 27.12 Immunoglobulin gene rearrangement in human B cells. Ig genes are arranged in tandem on three different chromosomes. (a) The H chain gene complex on human chromosome 14. The filled boxes represent Ig coding gene segments. The dashed lines indicate intervening sequences and are not shown to scale. (b) The κ light-chain complex on human chromosome 2. The λ light-chain genes are in a similar complex on human chromosome 22. (c) Assembly of one-half of an antibody molecule.

Genetic recombination occurs in each B cell during its development. One each of the V, D, and J segments is recombined at random to form a functional heavy-chain gene, while randomly recombined V and J segments form a complete light-chain gene. The active gene, still containing an intervening sequence between the VDJ or VJ gene segments and the C gene segments, is transcribed, and the resulting primary RNA transcript is spliced to yield the final messenger RNA (mRNA). The mRNA is then translated to make the heavy and light chains of the Ig molecule.

VDJ Recombination and Somatic Hypermutation

If one considers all of the random reassortments possible in genes encoding immunoglobulin heavy and light chains and from these calculates the number of unique molecules that could be encoded,

the total diversity is astonishing. In humans, for example, based on the numbers of kappa (κ) light-chain gene segments, there are about $40 V \times 5 J$ possible rearrangements, or 200 possible κ light chains. For the alternative lambda (λ) light chain, the type produced instead of κ by some B cells in every individual, there are about $30 V \times 4 J = 120$ possible combinations. About 10,500 possible heavy chains can be formed by the rearrangement of about $65 V \times 27 D \times 6 J$ genes. Assuming that each heavy chain and light chain has an equal chance to be expressed, there are $10,500 \times 200 = 2,100,000$ possible immunoglobulins with κ light chains and $10,500 \times 120 = 1,260,000$ possible immunoglobulins with λ chains. Therefore, at least 3,360,000 possible antibodies can be expressed based on random reassortment alone!

On top of this impressive diversity, additional diversity is generated in the CDR3 regions of both heavy and light chains by several unique mechanisms. First, the DNA-joining mechanism that constructs V-D or D-J gene segments in the heavy chain or the V-J gene segments in the light chain is an imprecise process. The final nucleotide sequence at these regions occasionally varies by a few nucleotides from the original genomic sequence, and when this occurs, it will alter the amino acid sequence in this region. Even more diversity is generated at V-D and D-J coding joints in the heavy-chain genes and at V-J coding joints in light-chain genes by either random (N) or template-specific (P) nucleotide additions. Because these coding joints are contained within the sequences that encode CDR3 on both heavy and light chains, N and P diversity at V-domain coding joints changes or adds amino acids in the CDR3 of both heavy and light chains.

VDJ recombination events are antigen-independent and occur as B cells develop in the bone marrow. In mature B cells that have migrated to lymphoid tissues, immunoglobulin diversity is further expanded upon antigen exposure by a process called **somatic hypermutation**—the mutation of B cell Ig genes at much higher rates than those observed in other genes. Somatic hypermutation of Ig genes is typically evident after a second exposure to an immunizing antigen and occurs only in the V regions of rearranged heavy- and light-chain genes, creating B cells with slightly altered Ig cell surface receptors. These mutated B cells compete for available antigen, and B cells whose receptors have a higher affinity for antigen than the original B cell receptor are selected. This process, called *affinity maturation*, is one of the factors responsible for a dramatically stronger secondary immune response (Figures 27.1c and 27.10). Affinity maturation also adds more diversity to the pool of antibody specificity in the adaptive immune response, thus making the potential antibody repertoire essentially infinite.

- Describe antigen binding to the CDR1, 2, and 3 regions of the heavy-chain and light-chain variable domains.
- Describe the recombination events that produce a mature heavy-chain gene and other somatic events that further enhance antibody diversity.

III • The Major Histocompatibility Complex (MHC)

The major histocompatibility gene complex (MHC) encodes cell surface proteins that present antigens to T cells, providing an important link between innate and adaptive immune mechanisms.

The major histocompatibility complex (MHC) is a series of genes found in all vertebrates that encodes a group of proteins important in antigen presentation. The MHC proteins in humans are called **human leukocyte antigens (HLAs)** and were first identified as the major antigens responsible for immune-mediated tissue transplant rejection. We now know that MHC proteins function primarily as antigen-presenting molecules, binding pathogen-derived peptides and displaying these peptides for interaction with T cell receptors.

27.5 MHC Proteins and Their Functions

The MHC proteins consist of two protein classes encoded by about 4 megabase pairs (Mbp) of DNA (**Figure 27.13a**). **MHC class I proteins** are expressed on the surfaces of all nucleated cells and function to present peptide antigens to *T-cytotoxic (T_c) cells*. If a peptide antigen presented by MHC class I is recognized by the TCR of a T_c cell, the antigen-containing cell is quickly destroyed (Section 27.8). **MHC class II proteins** are found only on the surface of B lymphocytes, macrophages, and dendritic cells—the antigen-presenting cells (APCs; ◀ Section 26.4). Through their MHC class II proteins, APCs present antigens to *T-helper (T_h) cells*, stimulating cytokine production that leads to antibody-mediated immunity or inflammatory responses (Section 27.8).

Class I and Class II MHC Proteins

Class I MHC proteins consist of the membrane-embedded *alpha* (α) chain, encoded by a gene located in the MHC gene region, and the *beta-2 microglobulin* (β_2m), a smaller, noncovalently associated protein encoded by a gene not included in the MHC gene cluster (Figure 27.13b and d). The α chain folds to form a peptide-binding groove that accommodates peptides of 8 to 11 amino acids (Figure 27.13d and e). The peptides in infected cells are derived from *endogenous* (intracellular) antigens, for example, from viral proteins produced inside the cell. Following translocation to the cell surface, the MHC–virus-peptide complexes are recognized by TCRs on activated T_c cells, and the T_c cells then kill the infected target cells.

Class II MHC proteins consist of two membrane-integrated polypeptides, α and β , expressed primarily by APCs. Together, one α and one β polypeptide form a functional heterodimer (Figure 27.13c, f). The $\alpha 1$ and $\beta 1$ domains of the MHC class II protein interact to form a binding site for TCR–peptide similar to the MHC class I binding site for TCR–peptide. However, the peptide-binding groove in the class II MHC is able to bind and display peptides that may be significantly longer than 8–11 amino acids. Peptides presented by class II MHCs are typically 10 to 20 amino acids long and are proteolytic fragments derived from *exogenous* (extracellular) antigens from pathogens that have been phagocytosed and digested by APCs. The APCs use the MHC class II–peptide complex to interact with TCRs on T_h cells, leading to T_h activation and an adaptive immune response (Section 27.8).

Antigen Processing and Presentation to T Cells

MHC proteins are expressed on cell surfaces only when they are complexed with a peptide, either a self peptide or a foreign peptide. In essence, then, *MHC–peptide complexes reveal to the immune system the protein composition of the cell* and, in this capacity, function to alert the immune system when a cell contains foreign antigens. T cells, through their TCRs, scan cell surfaces to identify any cells expressing foreign antigens as an indication of infection. When the latter are encountered, the TCR interacts with the foreign antigen presented on the MHC I protein, and this interaction targets the cell for destruction. T cells do not destroy cells presenting MHC–self peptide complexes because self-reactive T cells that escape clonal deletion in the thymus typically become anergic upon recognition of self antigens (Section 27.7).

Figure 27.13 Human leukocyte antigen (HLA) genes and MHC proteins. (a) The HLA complex, located on human chromosome 6, contains more than 4 megabase pairs (Mbp). Class II genes *DPA* and *DPB* encode class II proteins $DP\alpha$ and $DP\beta$; *DQA* and *DQB* encode $DQ\alpha$ and $DQ\beta$; *DRA* and two *DRB* loci encode $DR\alpha$ and $DR\beta$ proteins. The class I MHC proteins HLA-A, HLA-C, and HLA-B are encoded by genes *A*, *C*, and *B*. The class II and class I loci are highly polymorphic and encode

peptide-binding proteins. Class III MHC genes encode proteins associated with immune-related functions, such as complement proteins C4 and C2 and the cytokine TNF (tumor necrosis factor). (b) Schematic of MHC class I protein. The $\alpha 1$ and $\alpha 2$ domains interact to form the peptide antigen-binding site. (c) Schematic of MHC class II protein. The $\alpha 1$ and $\beta 1$ domains combine to form the peptide antigen-binding site. (d) MHC class I protein structure. Beta-2 microglobulin (β_2m)

binds noncovalently to the α chain. The antigen peptide (brown) is bound cooperatively by the $\alpha 1$ and $\alpha 2$ domains. (e) An MHC I protein with a bound peptide, as seen from above. A peptide of nine amino acids is shown as a molecular backbone structure embedded in a space-filling model of a mouse MHC I protein. (f) Structure of MHC class II protein dimer. The antigen peptide (brown) is shown embedded in the peptide-binding site of the MHC II proteins.

Two distinct antigen-processing schemes are at work to initiate adaptive immune responses: one for MHC I antigen presentation and another for MHC II antigen presentation. MHC I proteins present peptide from viruses or other intracellular pathogens; such infected cells are called *target cells* (Figure 27.14a). Proteins derived from infecting viruses, for example, are taken up and digested in the cytoplasm in a structure called the *proteasome*. Peptides about ten amino acids long are transported into the endoplasmic reticulum (ER) through a pore called the *transporter for antigen processing* (TAP). Once the foreign peptides have entered the ER they are bound by MHC I, and the MHC I–peptide complex moves to the cell surface where it integrates into the cell membrane. When the TCR on the surface of a Tc cell interacts with both the foreign peptide (recognized as “nonself”) and the MHC I protein (recognized as “self”) on the surface of the target cell, the Tc cell releases *perforin* and *granzyme*, cytotoxic proteins that kill the virus-infected target cell.

MHC II proteins are expressed on APCs, where they function to present peptide antigens from engulfed pathogens (Figure 27.14b). Similar to MHC I, MHC II proteins are assembled in the endoplasmic reticulum. In the ER, the MHC II peptide-binding groove is blocked by a protein called invariant chain (Ii) until the MHC II complex is situated in a lysosome (Figure 27.14b). After ingestion of a pathogen or a pathogen product by an APC, the phagosome containing the foreign antigen fuses with a lysosome to form a phagolysosome (◀ Section 26.7). Within the phagolysosome, enzymes digest both the foreign antigens and the Ii peptide but not MHC II. The foreign peptides are then loaded onto the newly freed MHC II peptide-binding groove, and the complex is inserted into the cell surface for presentation to T-helper cells. The latter, through their TCRs, recognize the MHC II–peptide complex and secrete cytokines that activate APCs, such as macrophages for enhanced phagocytosis or B cells for antibody production.

In addition to the TCR, each T cell expresses a unique cell surface protein that functions as a *coreceptor*. Tc cells express the **CD8 coreceptor**, and Th cells express the **CD4 coreceptor** (Figure 27.14). When the TCR binds to the peptide–MHC complex, the coreceptor on the T cell also binds to the MHC protein on the antigen-presenting cell, strengthening the molecular interactions between the cells and enhancing activation of the T cell. CD4 binds only to MHC II, strengthening Th cell interaction with APCs that express MHC II protein. Likewise, CD8 binds only to MHC I, enhancing the binding of Tc cells to MHC I–bearing target cells. In clinical medicine, the CD4 and CD8 proteins are used as T cell markers to differentiate Th (CD4) cells from Tc (CD8) cells in diagnostic tests, for example, in assessing the course of disease in an AIDS patient (▶ Section 31.15 and Figure 31.48).

We now consider the fact that human MHC proteins allow for some sequence variation from individual to individual and how this variation affects the immune response.

Check Your Understanding

- Identify the cells that display MHC class I and MHC class II proteins on their surfaces.
- Compare the MHC I and MHC II protein structures and peptide-binding sites. How do they differ? How are they similar?
- Define the sequence of events for processing and presenting antigens from both intracellular (endogenous) and extracellular (exogenous) pathogens.

27.6 MHC Polymorphism, Polygeny, and Peptide Binding

Although MHC class I and class II proteins theoretically can bind all possible antigen peptides for presentation to T cells, MHC proteins in different individuals of the same species are not identical. Different individuals typically have subtle differences in the amino acid sequence of homologous MHC proteins. These genetically encoded MHC variants, called *polymorphisms*, are the major immunological barriers for successful tissue transplantation from one individual to another.

Polymorphism, Polygeny, and the Immune Barrier to Tissue Transplantation

Polymorphism is the occurrence, within a population, of multiple alleles (alternate forms of a gene) at a specific *locus* (the location of the gene on the chromosome). For example, the MHC class I locus *HLA-A* (Figure 27.13a) has over 2000 known alleles, each of which encodes a distinct HLA-A protein that occurs within the human population. The genome of each person, however, contains only two of the *HLA-A* alleles; one allele is of paternal origin and one is of maternal origin. The two allelic protein products are expressed equally (Figure 27.15a).

Additional MHC class I protein diversity is a result of **polygeny**, in which evolutionary gene duplication events have led to the occurrence of two additional genetically, structurally, and functionally related loci, *HLA-B* and *HLA-C*. These gene loci are also polymorphic, having more than 2600 and 1500 allelic variants, respectively. Thus, an individual typically displays six structurally distinct proteins derived from the three polymorphic class I loci (three products derived from maternal origin and three products derived from paternal origin) (Figure 27.15b). Likewise, highly polymorphic and equally expressed alleles encode MHC class II proteins at the *HLA-DR*, *HLA-DP*, and *HLA-DQ* alpha- and beta-chain loci (Figure 27.13a).

As a result of polymorphism and polygeny, most individuals have unique MHC profiles. Only closely related family members are likely to have all of the same MHC genes and proteins, and this property can be used to prove (or disprove) paternity and has also been used to trace ancestral lineages and pathways of early human migration (Figure 27.16). These highly polymorphic variations in MHC proteins are major barriers to successful tissue transplants because the MHC proteins on the donor tissue (graft) are recognized as foreign by the recipient’s immune system. An immune response directed against the graft MHC proteins thus causes rejection and death of the graft tissue. However, matching MHC alleles between donors and recipients minimizes tissue graft rejection. Control of tissue rejection may also be accomplished by administering drugs that suppress the immune system.

Peptide Antigen Binding

Most of the allelic variations in MHC proteins occur as amino acid changes concentrated in the peptide-binding groove (Figure 27.13d–f), and each polymorphic variation of the MHC protein binds a different set of peptide antigens. The peptides bound by a single MHC protein share a common structural pattern—a peptide **motif**—and each different MHC protein binds a different motif. For example, for a certain MHC class I protein, the bound peptides contain eight

Figure 27.14 Antigen presentation by MHC I and MHC II proteins. (a) ① Protein antigens, such as virus components manufactured within the cell, are degraded by the proteasome in the cytoplasm. The peptide fragments are transported into the endoplasmic reticulum (ER) through a pore formed by the TAP proteins. ② MHC I proteins in the ER are stabilized by chaperonins until peptide fragments are bound. ③ When peptide fragments are bound by MHC I, the complex is transported to the cell surface. ④ The MHC I–peptide complex interacts with T cell receptors (TCRs)

on the surface of Tc cells. ⑤ The CD8 coreceptor on the Tc cell engages MHC I, resulting in a stronger complex. The Tc cell is activated by the binding events, causing it to release cytokines and cytolytic toxins and kill the target cell. (b) ① External foreign proteins are imported into the cell and digested into peptide fragments in phagolysosomes. ② MHC II proteins in the ER are assembled with Ii, a blocking protein that prevents MHC II from binding with peptides in the ER. ③ The MHC II–Ii assembly is transported to the lysosome, where it remains until the lysosome fuses with

the phagosome, forming a phagolysosome where Ii is degraded, ④ freeing the MHC II protein to bind the foreign peptide fragments. ⑤ The MHC II–peptide complex is transported to the cell surface, where it interacts with TCRs and ⑥ the CD4 coreceptor on Th cells. The Th cells then release cytokines that interact with other cells to promote an immune response. Note that the APC in part b may be either a B cell, which ingests antigen by endocytosis (shown), or a macrophage or dendritic cell, which engulf antigens through phagocytosis.

Figure 27.15 Polymorphism and polygeny in MHC genes and proteins. (a) Polymorphism in *HLA-A* loci results in equal expression of proteins encoded by both alleles. There are over 2000 *HLA-A* alleles in the human population, but only two (one at each locus) are found in each individual. *HLA-B* and *HLA-C* exhibit similar levels of polymorphism. (b) Polygeny in MHC results in duplicated polymorphic *HLA-A*, *HLA-B*, and *HLA-C* genes that potentially encode three pairs of different MHC proteins. The colors represent alternate alleles of each gene and their respective protein.

amino acids with a phenylalanine (F) at position 5 and a leucine (L) at position 8 (◀ Figure 6.27 for the structures of amino acids). All other positions in the peptide can be occupied by any amino acid (designated by an X). Thus, all peptides sharing the sequence X-X-F-X-X-L would bind to that MHC protein. Another MHC class I protein encoded by a different MHC allele binds a peptide motif of nine amino acids with a tyrosine (Y) at position 2 and an isoleucine (I) at position 9 (X-Y-X-X-X-X-X-I).

The invariant amino acids in each motif are called *anchor residues*—they bind directly and specifically within an individual

MHC peptide-binding groove. Thus, an individual MHC protein can bind and present many different peptide antigens if the peptides contain the same anchor residues. Because each MHC protein binds a different motif with different anchor residues, the six possible MHC I proteins encoded in an individual's genome bind six different motifs. In this way, each individual can present a large number of different peptide antigens using the limited number of MHC I molecules available. MHC II proteins bind peptides in a similar manner.

Because of polymorphisms and polygeny within the human species, at least a few peptide antigens from virtually any pathogen will display a motif that can be bound and presented by the MHC proteins. This system of generating antigen-binding diversity is therefore quite different from the genetic mechanisms used to synthesize Igs (Section 27.4) and TCRs (Section 27.7), in which each receptor interacts specifically with only a *single* antigen or antigenic determinant.

Check Your Understanding

- Define polymorphism and polygeny as they apply to MHC genes.
- How does a single MHC protein present many different peptides to T cells?

Figure 27.16 Polymorphic *HLA* genes and tracing ancestral lineages. The image shows what a Neanderthal man might have looked like. By analyzing the distribution of specific *HLA* alleles within different populations, researchers are increasingly able to reconstruct migration and interbreeding patterns of ancient humans and other hominids, including as far back as the Neanderthal era. The intermixing of *HLA* genes between disparate ancient populations increased genetic diversity and likely enhanced survival by helping to strengthen and shape the modern immune response.

IV • T Cells and Their Receptors

There are many different classes of T cells, and each class carries out specific functions. Using their T cell receptors, T cells of various types interact with antigens presented on MHCs to initiate and implement an adaptive immune response to pathogen invasion.

Adaptive immunity is ultimately initiated by the recognition of foreign peptides on infected cells by T lymphocytes. The infected cells that are first recognized by T cells may include the same phagocytes that participate in the innate immune response (Chapter 26). Antigen presentation activates *naïve* (uncommitted) T lymphocytes to differentiate into effector T cells that carry

out cell-mediated immunity. In the absence of antigen-activated T cells, there is little antigen-specific immunity and no immune memory.

27.7 T Cell Receptors: Proteins, Genes, and Diversity

APCs ingest bacteria, viruses, and other antigenic material by phagocytosis (in the case of macrophages and dendritic cells) or through internalization of a molecular antigen bound to a BCR. Phagosomal or cytoplasmic antigens are then digested, complexed with MHC proteins, and moved to the cell surface for antigen presentation to T cells. The TCRs of T cells can recognize (bind) antigens only when the peptides are complexed with MHC proteins on host cell surfaces. For example, a macrophage or dendritic cell that has encountered a virus will display MHC I and MHC II proteins embedded with viral peptides (Figure 27.17). These viral peptide–MHC complexes are the sites for T cell activation and interaction.

Each T cell expresses a TCR that is specific for a single peptide–MHC complex. Antigen-specific T cells are found closely associated with APCs in the spleen, lymph nodes, and MALT. T cells constantly sample surrounding APCs for peptide–MHC complexes. Peptide–MHC complexes that interact with the TCR signal the T cell to grow and divide, producing antigen-reactive clones that coordinate cell-mediated killing, induce inflammation, and activate antibody-producing B cells. Here we examine how the TCR interacts with antigens presented on an APC or an infected target cell.

Figure 27.17
T cell immunity

Figure 27.17 T cell-mediated immunity. Antigen-presenting cells, such as the phagocytes in innate immunity, ingest, degrade, and process antigens. They then present antigens to T cells that secrete protein cytokines that activate the adaptive immune response. T-helper 1 (Th1) cells produce cytokines that activate other cells and induce inflammation. T-cytotoxic (Tc) cells produce perforin and granzyme, proteins that destroy nearby target cells.

TCR Structure and Diversity

The TCR is a membrane-spanning protein that extends from the T cell surface into the extracellular environment. Similar to B cells with their BCRs, each T cell has thousands of copies of its specific TCR on its surface. A functional TCR consists of an α and a β polypeptide chain, and like Igs, each TCR chain has a variable (V) domain and a constant (C) domain (Figure 27.18). The V_α and V_β domains interact cooperatively to form an antigen-binding site that contains complementarity-determining region (CDR1, CDR2, and CDR3) segments. However, unlike Igs, which can bind antigens in a native conformation, *TCRs recognize only peptides bound to self MHC*; other antigens, such as complex polysaccharides, are not recognized by TCRs.

The three-dimensional structure of the TCR bound to MHC I–peptide is shown in Figure 27.18a. Both TCR and MHC proteins bind directly to peptide antigen. The MHC protein binds one face of the peptide—the MHC motif—and the TCR binds the other peptide face—the T cell epitope (Figure 27.18b). The CDR regions of the TCR bind directly to the MHC–peptide complex, and each CDR has a specific binding function. The CDR3 regions of the TCR α and β chains bind the antigen epitope; the CDR1 and CDR2 regions of the TCR α and β chains bind mainly to the MHC protein.

The adaptive immune response can generate TCR diversity sufficient to bind nearly every possible peptide antigen generated by APCs or target cells. T cells generate receptor diversity in ways similar to the generation of Ig diversity in B cells, and Table 27.3 compares the receptor diversity-generating mechanisms for each cell type. Analogous to the H and L chains of Igs, the TCR α and β chains are encoded by distinct constant- and variable-domain gene segments. TCR V-region gene segments are grouped together sequentially; those encoding the α chain include 80 V and 61 J segments, whereas those encoding the β chain include 52 V, 2 D, and 13 J gene segments (Figure 27.19). As we have seen for Igs (Section 27.4), antigen-binding diversity in TCRs is generated by somatic recombination, imprecise V–J (α -chain) or V–D–J (β -chain) joining, and random reassortment. Additional TCR diversity is generated because the D region of the β chain can be transcribed in all three reading frames (Section 6.9 and Figure 6.34), leading to production of three separate transcripts from each D-region gene segment.

Similar to the assembly of Ig H and L chains, individual α and β chains are produced by each T cell at random and assembled to form the $\alpha\beta$ heterodimer. The somatic hypermutation mechanisms responsible for increased receptor diversity in Ig genes do not operate in T cells, and thus additional TCR diversity from these events is not possible. Despite this, potential TCR diversity is still enormous; an estimated 10^{15} different TCRs can be generated! It is important to note that not all TCR interactions with MHC–peptide result in activation of the T cell. As we now consider, many T cells that escape deletion in the thymus never receive the full set of activation signals necessary to become effector cells.

T Cell Activation and Anergy

Like B cells, T cells require a second signal for activation in addition to interactions with MHC–peptide. As we described in Section 27.1, T cells that react strongly with self antigens are deleted in the thymus to prevent autoimmunity. However, many self antigens are not

Figure 27.18 The TCR:MHC I-peptide complex. (a) A three-dimensional structure showing the orientation of TCR, peptide (brown), and MHC. This structure was derived from data deposited in the Protein Data Bank. (b) A diagram of the TCR:MHC-peptide structure. Note that the peptide is bound by both MHC and TCR proteins and has a distinct surface structure that interacts with each (a motif interacts with the MHC and an epitope with the TCR, as discussed in the text).

Figure 27.19 Organization of the human TCR α - and β -chain genes. The α -chain gene segments are located on chromosome 14, and the β -chain gene segments are on chromosome 6. Compare this figure with Figure 27.12.

expressed in the thymus, meaning that many T cell clones responsive to nonthymus self antigens avoid deletion. Yet, because of the requirement of a second signal for activation, these self-reactive T cells remain unresponsive and become anergic after they leave the thymus.

T cells that migrate from the thymus to secondary lymphoid organs and have not yet encountered specific antigen are naive and must be activated to become competent effector cells. For example, the first requirement for activation of a naive Tc cell is TCR binding of an MHC–peptide complex presented by an APC (**Figure 27.20a**). The next step requires the interaction of two more proteins: B7, found on the APC, and CD28, expressed on the surface of the Tc cell. The binding of B7 to CD28 is the second signal necessary to activate the Tc cell and make it an effector cell; without the B7–CD28 interaction, the naive Tc cell is not activated (**Figure 27.20**). Once a T cell is activated, only the first signal (TCR binding to MHC–peptide) is required to induce an effector T cell. Thus, the activated (effector) Tc cell in **Figure 27.20b** can kill any target cell presenting the recognized peptide antigen on its MHC I, even those cells that do not display B7.

Figure 27.20 T cell activation. (a) A naive Tc cell interacts through its TCR with an MHC–peptide presented by an APC, the first required activation signal. In addition, CD28 on the Tc cell interacts with B7 on the APC, the second signal required to activate the naive T cell. (b) The activated Tc cell can kill any target cell bearing the same MHC–peptide. (c) A naive Tc cell interacts through its TCR with an MHC–peptide presented by any cell. Conditions for the first signal are met, but the second signal is not generated because only APCs display the B7 protein. (d) In the absence of the second signal, the Tc cell becomes permanently unresponsive, or *anergized*.

The requirement for a second activation signal has major implications for establishing and maintaining clonal anergy. A naive Tc cell that interacts with a self antigen on a cell that is not an APC will receive only an MHC–peptide signal because non-APCs do not express B7. In the absence of the B7–CD28 interaction, a T cell that engages MHC–peptide is permanently anergized and can never be activated (**Figure 27.20c and d**), thus providing protection against harmful autoimmune reactions.

Structural Similarities of Antigen-Binding Proteins

As we have seen, antigen-binding proteins of the adaptive immune response have common structural features. Ig, TCR, and MHC protein complexes all consist of two nonidentical polypeptides: MHC and TCR proteins are composed of α and β polypeptide chains, and Igs have separate heavy and light chains (**Section 27.4**). Therefore, these protein complexes are believed to have arisen from duplication and selection of genes encoding primordial antigen receptors. Because of their shared structural, evolutionary, and functional features, genes encoding Ig, TCR, and MHC proteins are part of an extended gene family called the **immunoglobulin gene superfamily**, and a comparison of Ig superfamily proteins is shown in **Figure 27.21**.

The constant (C) domain of each protein in the superfamily has a highly conserved amino acid sequence consisting of about 100 amino acids with an intrachain disulfide bond spanning 50–70 amino acids. C domains provide structural integrity for the antigen-binding molecules, anchor the antigen-binding V domains to the cytoplasmic membrane, and give each protein its characteristic shape. C domains can also provide recognition sites for accessory molecules. For example, C domains of most IgG and all IgM proteins are bound by the C1q component of complement, a critical first step in initiating the classical complement activation sequence (**Section 26.9**). Likewise, MHC I C domains bind to the accessory CD8 protein on Tc cells, and homologous MHC II C domains bind CD4 on Th cells. As we have discussed, such interactions are critical steps for T cell activation and initiation of adaptive immunity (**Section 27.5**).

The variable (V) domains of TCR and Ig molecules are about the same length as the C domains, but the structures of V domains can vary considerably from one another and from C domains. As we have seen, Ig and TCR V domains interact specifically with a nearly limitless variety of antigens, whereas the V domains of MHC proteins, which have likely evolved independently of Ig and TCR V domains, interact with foreign peptides that share a common motif (**Section 27.6**).

Although all T cells produce and express antigen-binding TCRs, T cells are not all functionally equivalent. As we will see next, there are several different subsets of T cells, each with their own specific functions in the adaptive immune response.

Check Your Understanding

- Identify diversity-generating mechanisms unique to TCRs as compared to diversity-generating mechanisms in Igs.
- What does it mean when a T cell becomes “anergized,” and how does this process relate to the prevention of autoimmunity?
- Describe and compare the structural features of Ig gene superfamily constant and variable domains.

Figure 27.21 Immunoglobulin gene superfamily proteins. Constant (C) domains have homologous amino acid sequences and higher-order structures. The Ig-like C domains in each protein chain indicate evolutionary relationships that identify the proteins as members of the Ig gene superfamily. The variable (V) domains of Igs and TCRs are also Ig-like, but the peptide-binding domains of MHC class I and class II proteins (green) are not because their structures vary considerably from the basic features of the Ig domain.

27.8 T Cell Subsets and Their Functions

Antigen-reactive T cells consist of multiple T cell subsets having different functional properties. As we have discussed, **T-cytotoxic (Tc) cells**, also called *cytotoxic T lymphocytes (CTLs)*, are CD8 T cells (Section 27.5) that recognize the peptide–MHC I complex on an infected cell. By contrast, **T-helper (Th) cells**, which can differentiate into several more specialized Th cell subsets, are CD4 T cells that interact with peptide–MHC II complexes on the surface of APCs and function to activate macrophages and stimulate antibody-mediated immunity.

T-Cytotoxic Cells

When an effector Tc cell (a CTL) recognizes a foreign peptide on an infected cell, it kills the peptide-bearing target cell. For example, a viral peptide embedded in MHC I, displayed on a virus-infected cell, marks the cell for interaction and killing by a CTL whose TCRs recognize the viral antigen. Contact between a CTL and the target cell is required to initiate killing of the infected cell (**Figure 27.22a**). The point of initial contact is between the TCR and the peptide–MHC I complex. The CD8 protein on the CTL then binds the MHC I protein, strengthening the interaction and establishing an *immunological synapse* between the two cells. In addition to engaging and destroying virus-infected host cells, CTLs also have the ability to identify and kill cancer cells that present abnormal peptides (**Figure 27.22b**).

Upon contact with the target cell, granules in the CTL migrate to the contact site, where the contents of the granules—cytolytic proteins called *perforin* and *granzyme* (Section 27.5)—are released into the synapse (**Figure 27.22**). Perforin molecules enter the membrane of the target cell and combine to form a transmembrane pore through which granzyme molecules then enter the target cell. Granzymes are cytotoxins that induce *apoptosis* (programmed cell death), characterized by organized killing and degradation of the target cell from within. The released perforin and granzyme molecules affect only the target cell because degranulation within the synapse is confined to the contact surface between the CTL and the target cell

bearing peptide–MHC I. Cells lacking the peptide recognized by the CTL do not make contact and are not killed.

Different Classes of T-Helper Cells

Interactions with APCs drive naive CD4 Th cells to differentiate into one of several Th subsets, each producing unique combinations of cytokines that direct the immune response (**Table 27.4**). Dendritic cells and, to a lesser extent, macrophages (◀ Section 26.4) play a central role as APCs in the activation of Th cells. A naive

Figure 27.22 T-cytotoxic cells. (a) When the TCR on a cytotoxic T lymphocyte (CTL) binds MHC I–peptide complexes on any cell, degranulation of the CTL releases molecules of perforin and granzyme, cytotoxins that perforate the target cell and cause apoptosis, respectively. (b) Three CTLs containing granules of perforin and granzyme (red) surround a cancer cell (blue, center). The CTL on the top left is in the process of flattening its membrane surface (green) against the cancer cell to form the immunological synapse.

TABLE 27.4 T-helper cell subsets				
Characteristic	Th1	Th2	Th17	Treg
Antigen-presenting cell	Macrophage	B cell	Activated dendritic cell	Nonactivated dendritic cell
Major cytokines produced	IL-2, IFN- γ , TNF- α	IL-4, IL-5	IL-17, IL-6	IL-10, TGF- β
Cellular effects	Activation of T cells (IL-2) and macrophages	Activation of B cells	Activation and recruitment of neutrophils	Suppression of adaptive immune cells
Systemic effects	Cell-mediated immunity	Antibody-mediated immunity	Amplification of innate immunity	Control of Th immunity

Th cell that recognizes peptide–MHC II through its TCR and also receives the costimulatory B7–CD28 second signal (Section 27.7) is further stimulated by the release of cytokines from the APC. This causes the Th cell to proliferate and differentiate into long-lived memory cells and effector Th cells that enter the circulation and migrate to sites of infection. The population of effector Th cells is comprised of different Th cell subsets, which may include *Th1*, *Th2*, and *Th17* cells.

Th1 cells produce IL-2, a cytokine that promotes growth and activation of other T cells, and also activate macrophages through the cytokines interferon gamma (IFN- γ), tumor necrosis factor alpha (TNF- α), and granulocyte–monocyte colony-stimulating factor (GM-CSF) (Figure 27.23a). Th1-activated macrophages take up and kill foreign cells more efficiently than nonactivated (resting)

macrophages (Figure 27.23b), and they may also kill tumor cells because activated macrophages recognize as nonself the tumor-specific antigens expressed by cancer cells.

Activated macrophages also produce several cytokines and chemokines that function as proinflammatory mediators and chemoattractants, respectively. Table 27.5 summarizes the source and activities of these and other important immune cytokines and chemokines. In the case of organ or tissue transplants, Th1-activated macrophages can actually harm the host if the host’s Th1 cells recognize nonself MHC proteins on the transplant and trigger macrophage activation and transplant destruction (Section 27.6).

Th2 cells play a pivotal role in B cell activation and antibody production. As we have discussed (Section 27.3), B cells make antibodies, and differentiated B cells are coated with antibodies (BCRs)

Activated Th1 cells produce cytokines that activate macrophages, leading to increased phagocyte activity and inflammation. (b) Activated macrophages are generally larger than resting macrophages and have a ruffled surface, often with cytoplasmic extensions that “feel” for pathogens. In addition to carrying out more aggressive phagocytosis, activated macrophages express genes that encode bactericidal enzymes found in lysosomes, such as proteases and enzymes that produce reactive oxygen species, all of which are designed to quickly kill ingested microorganisms inside the phagolysosome (◀ Figure 26.11).

that function as antigen receptors. When antigen binds the BCR (Figure 27.6), the antibody-bound antigen is taken into the B cell by endocytosis and degraded. Peptides from the degraded antigen are then loaded into the B cell’s MHC II protein for presentation to a Th2 cell. The Th2 cell responds by producing IL-4 and IL-5, cytokines that activate the B cell (Table 27.5) and cause it to proliferate and differentiate into plasma cells that produce and secrete antibodies specific to the presented antigen (Section 27.3).

Th17 cells are important in the first stages of the immune response. Naive Th cells differentiate into Th17 cells primarily through the activity of dendritic cells. When dendritic cells encounter pathogens, they present antigen and secrete IL-6 and transforming growth factor- β (TGF- β), cytokines that catalyze differentiation of naive Th cells to Th17 cells (Figure 27.24a). Th17 cells then produce IL-17, a cytokine that activates other tissue cells to produce cytokines and chemokines that attract proinflammatory neutrophils to the site of infection (Table 27.5). Thus, the function of Th17 cells is to produce IL-17, starting a cascade that draws neutrophils to infection sites. By recruiting neutrophils, Th17 cells amplify innate immunity triggered by interaction of a pathogen with the dendritic cell.

We conclude our consideration of T cells with a description of the **T regulatory (Treg) cell**, a Th cell subset that plays a critical role in *controlling* the immune response. Undifferentiated Th cells remain naive unless they are stimulated to mature and differentiate by certain cytokines, as is the case for IL-6 stimulation to produce Th17

cells. However, in the absence of a pathogen, Th cells can still interact with dendritic cells through MHC II–peptide–TCR (Figure 27.24b). In this case, the peptide is usually a self peptide, and an immune response to it could trigger autoimmunity. However, because the dendritic cells did not interact with a pathogen, they cannot produce IL-6 to promote Th17 differentiation. Instead, the absence of IL-6 pushes differentiation to Treg cells that make IL-10 and TGF- β , two cytokines that suppress immunity and inflammation. In the presence of self antigens and in the absence of IL-6, Treg cells shut down the immune response and inhibit inflammation. This is important for controlling immune responses to self antigen and preventing autoimmunity. In this regard, Treg cells play a key role in the maintenance of a healthy gut by interacting with short-chain fatty acids produced by the normal colonic microbiota to suppress host inflammatory responses against these “friendly” bacteria (◀ Section 24.9 and Figure 24.23).

CHAPTER REVIEW

I • Principles of Adaptive Immunity

27.1 The adaptive immune response is characterized by *specificity* for the antigen, the ability to respond more vigorously when reexposed to the same antigen (*memory*), and the acquired inability to interact with self antigens (*tolerance*). Tolerance in lymphocytes is acquired through a selection process. Immature T cells that do not interact with MHC–peptide (positive selection) or that react strongly with self antigens (negative selection) are eliminated by clonal deletion in the thymus. T cells that survive positive and negative selection leave the thymus and can participate in the immune response. Lymphocyte reactivity to self antigens is controlled through clonal deletion and anergy.

Q Why is it necessary for immature T lymphocytes to undergo a two-step selection process through which antigen-reactive cells are first selected followed by the elimination of cells that react strongly with self-antigens?

27.2 Immunogens are foreign macromolecules that induce an immune response. Immunogens initiate an immune response when introduced into a host. Antigens are molecules

recognized (bound) by antibodies or TCRs. Adaptive immunity develops naturally and actively through immune responses to infections, or naturally and passively through antibody transfer from the placenta or breast milk. Artificial passive immunity occurs when antibodies or immune cells are transferred from an immune individual to a nonimmune individual. Immunization induces artificial active immunity and is widely used to prevent infectious diseases.

Q Immunity can be of many types: natural active immunity, natural passive immunity, artificial active immunity, and artificial passive immunity. Which of these forms of immunity confer immune memory?

II • Antibodies

27.3 Antibody production is initiated when an antigen contacts an antigen-specific B cell. Whereas B cell activation from T-independent antigens requires no T cell help, B cells that bind T-dependent antigens must process the antigen and present it to an antigen-specific Th cell. The Th cell becomes activated, producing cytokines that signal the B cell to clonally

expand and differentiate to produce soluble, antigen-specific antibodies. Each antibody (immunoglobulin) protein consists of two heavy and two light chains. The antigen-binding site is formed by the interaction of the variable regions of one heavy and one light chain. Each antibody class has different structural characteristics, expression patterns, and functional roles. Clones of activated B and T cells can live for years as memory cells and can rapidly expand and differentiate to produce high titers of antibodies after reexposure to antigen.

Q Describe the structural and functional differences among the five major classes of antibodies. What cellular and molecular interactions occur to initiate production of antibodies?

- 27.4** The antigen-binding site of an immunoglobulin (Ig) is composed of the V (variable) domains of one heavy chain and one light chain. Each V region contains three complementarity-determining regions, or CDRs, that are folded together to form the antigen-binding site. Ig diversity is generated by several mechanisms. Somatic recombination of gene segments allows shuffling of the various Ig gene segments. Random re-assortment of the heavy- and light-chain genes, imprecise joining of VDJ and VJ gene segments, and hypermutation mechanisms contribute to nearly unlimited Ig diversity.

Q Which Ig chains are used to construct a complete antigen-binding site? Which domains? Which CDRs? Calculate the total number of germ-line-encoded V_H and V_L domains that can be constructed from the available Ig genes.

III • The Major Histocompatibility Complex (MHC)

- 27.5** T cells, with their TCRs, bind peptide antigens presented by MHC proteins on infected cells or APCs. Class I MHC proteins are expressed on all nucleated cells and present endogenous antigenic peptides to TCRs on Tc cells. Class II MHC proteins are expressed only on APCs. They function to present exogenously derived peptide antigens to TCRs on Th cells. These interactions activate T cells to kill antigen-bearing cells or to promote inflammation or antibody production.

Q Describe the basic structure of class I and class II major histocompatibility complex (MHC) proteins. In what functional ways do they differ?

- 27.6** Class I and class II MHC genes are highly polymorphic, and the many allelic variations challenge successful tissue

transplantation. Different alleles of MHC class I and class II genes encode proteins that bind and present different peptide subsets, each characterized by a specific structural motif.

Q For the MHC class I polymorphisms, how many different MHC proteins are expressed in an individual? How many by the entire human population?

IV • T Cells and Their Receptors

- 27.7** T cell receptors bind to peptide antigens presented by MHC proteins. The CDR3 regions of both the α chain and the β chain bind to the antigen epitope; the CDR1 and CDR2 regions bind to the MHC protein. VDJ gene segments encode the β -chain V domain of TCRs, and VJ gene segments encode the α -chain V domain. TCR diversity, generated by a variety of mechanisms, is nearly unlimited. The immunoglobulin gene superfamily encodes proteins that are evolutionarily, structurally, and functionally related to immunoglobulins. The antigen-binding Igs, TCRs, and MHC proteins are members of this superfamily.

Q What diversity-generating mechanisms function to produce the nearly unlimited variety of antigen-specific TCRs? What structural and functional features are common to proteins classified within the immunoglobulin gene superfamily?

- 27.8** T-cytotoxic (Tc) cells recognize antigens on virus-infected host cells and tumor cells through antigen-specific TCRs, and recognition triggers killing via perforin and granzyme. T-helper (Th) cells differentiate into several subsets. Through the action of cytokines, Th1 inflammatory cells activate macrophage effector cells, whereas Th2 cells activate B cells. Th17 cells are activated by pathogen-activated dendritic cells and secrete IL-17 to recruit neutrophils to the site of infection. Treg cells produce cytokines that suppress adaptive immunity.

Q What mechanism do Tc cells use to identify and destroy infected cells in the body? How do Th cells differ from Tc cells, and how do the different subsets of Th cells differ from each other?

APPLICATION QUESTIONS

- Antibodies of the IgA class are probably more prevalent than those of the IgG class. Explain why this might be the case. What benefits might this have for the host?
- Although genetic recombination events are important for generating significant diversity in the antigen-binding site of Igs, post-recombination somatic events may be even more important in achieving overall Ig diversity. Do you agree or disagree with this statement? Explain.
- Polymorphism implies that each different MHC protein binds a different peptide motif. However, for the MHC class I proteins, only 6 peptide motifs can be recognized in an individual, whereas over 6000 motifs can be recognized by the entire human population. What advantage does recognition of multiple motifs have for the individual? What potential advantage does recognition of the extremely large number of motifs have for the population? Can everyone process and present the same antigens?

CHAPTER GLOSSARY

Antigen a molecule capable of interacting with specific components of the immune system and that often functions as an immunogen to elicit an adaptive immune response

B cell receptor (BCR) a cell surface immunoglobulin that acts as an antigen receptor on a B cell

CD4 coreceptor a protein found on Th cells that interacts with MHC II on an antigen-presenting cell

CD8 coreceptor a protein found exclusively on Tc cells that interacts with MHC I on a target cell

Clonal anergy the inability to produce an immune response to specific antigens due to the neutralization of effector cells

Clonal deletion for T cell selection in the thymus or B cell selection in the bone marrow, the elimination by apoptosis of useless or self-reactive precursor lymphocytes

Clonal expansion following its activation, the proliferation and differentiation of a naive T or B lymphocyte into a clone of effector cells

Clone lymphocytes of identical antigen specificity that have arisen from a single, activated progenitor cell

Complementarity-determining region (CDR) a varying amino acid sequence within the variable domains of immunoglobulins or T cell receptors where contacts with antigen are made

Epitope the portion of an antigen that reacts with a specific antibody or T cell receptor

Human leukocyte antigen (HLA) an antigen-presenting protein encoded by a

major histocompatibility complex gene in humans

Immune memory (memory) the ability to rapidly produce large quantities of specific immune cells or antibodies after subsequent exposure to a previously encountered antigen

Immunogen a molecule capable of eliciting an adaptive immune response

Immunoglobulin gene superfamily a family of genes that are evolutionarily, structurally, and functionally related to immunoglobulins

Memory cell a long-lived B or T lymphocyte responsive to a specific antigen

MHC class I protein an antigen-presenting molecule found on all nucleated vertebrate cells

MHC class II protein an antigen-presenting molecule found on macrophages, B cells, and dendritic cells

Motif in antigen presentation, a specific amino acid sequence found in all peptides that bind to a given MHC protein

Negative selection in T cell selection, the deletion of T cells that interact strongly with self antigens in the thymus (see also *clonal deletion*)

Polygeny the occurrence of two or more genetically, structurally, and functionally related gene loci due to an evolutionary gene duplication event

Polymorphism in a population, the occurrence of multiple alleles for a gene locus at a higher frequency than can be explained by recent random mutations

Positive selection in T cell selection, the growth and development of T cells that interact with self MHC–peptide in the thymus

Primary immune response the production of antibodies or immune T cells on first exposure to antigen; the antibodies are mostly of the IgM class

Secondary immune response the enhanced production of antibodies or immune T cells on second and subsequent exposures to antigen; the antibodies are mostly of the IgG class

Somatic hypermutation the mutation of immunoglobulin genes at rates higher than those observed in other genes

Specificity the ability of cells of the adaptive immune response to interact with particular antigens

T cell receptor (TCR) an antigen-specific receptor protein on the surface of T cells

T-cytotoxic (Tc) cell a lymphocyte that interacts with MHC I–peptide complexes through its T cell receptor and produces cytotoxins that kill the interacting target cell

T-helper (Th) cell a lymphocyte that interacts with MHC II–peptide complexes through its T cell receptor and produces cytokines that act on other cells. Th subsets include **Th1** cells, which activate macrophages; **Th2** cells, which activate B cells; **Th17** cells, which activate neutrophils; and **Treg** cells, which suppress adaptive immunity

Tolerance the acquired inability to produce an immune response to particular antigens

Vaccination (immunization) the inoculation of a host with inactive or weakened pathogens or pathogen products to stimulate protective active immunity

Preventing Autoimmunity with . . . Parasitic Worms?

Some immune disorders are a result of *autoimmunity*, a harmful condition in which an immune response is directed against “self” antigens. For example, type 1 diabetes (T1D) is an autoimmune disorder in which immune cells attack and destroy insulin-secreting β cells in the pancreas, resulting in an inability to metabolize sugars and control blood glucose levels. With no cure, type 1 diabetics must treat their condition by strict diet control and regular injection (or subcutaneous infusion) of insulin.

The prevalence of T1D has risen markedly in recent years; currently, nearly 80,000 children around the world are diagnosed annually. Interestingly, most of these cases occur in developed nations associated with elevated socioeconomic conditions and modern sanitation. The “hygiene hypothesis” has been offered as an explanation for the rising prevalence of autoimmune diseases. The hypothesis asserts that the overly sanitized, primarily indoor upbringing typical for those in developed nations precipitates the onset of allergies and autoimmunity due to reduced early exposure to parasites and other microbes that traditionally associate with humans and shape immune development.

In this connection, researchers have reported that infection with parasitic helminths such as *Schistosoma mansoni* (photo), the causative agent of schistosomiasis, may improve and even prevent T1D. Recent studies have shown that *Schistosoma* infection can suppress Th1 cell activation and instead trigger the propagation of regulatory T (Treg) cells, thereby inhibiting inflammation and controlling the immune response. A similar helminth-mediated immune dampening has been demonstrated for other autoimmune disorders, such as the treatment of Crohn’s disease by introducing whipworm (*Trichuris suis*) infection.

These studies suggest that short-term parasitic worm infection (cured using antihelminthic drugs) may bring about long-term autoimmune protection. The next step is to determine what components of the worms actually cause the immunoregulatory effect so that it might become possible to administer only those purified products and avoid the intentional helminth infection.

Source: Tang, C.-I., et al. 2019. Helminths protect against type 1 diabetes: Effects and mechanisms. *Parasitol. Res.* 118: 1087. doi:10.1007/s00436-019-06247-4.

We discussed the key features of the innate and adaptive immune responses in Chapters 26 and 27, respectively, but of course the immune system does not always effectively halt microbial infection and disease progression. In fact, the immune response itself can be detrimental if self antigens are targeted. Such events cause immune disorders and immunodeficiency syndromes, which we explore in the first part of this chapter. We then discuss strategies to both prevent and treat diseases by either optimizing the immune response through vaccinations and immunotherapy or administering antimicrobial drugs to kill or inhibit established pathogens. We conclude the chapter with a discussion of the important implications of antimicrobial drug resistance.

Immediate
hypersensitivity

I • Disorders and Deficiencies of the Immune System

In some cases, the immune system fails to provide an adequate or beneficial response, and this may result in hypersensitivity, autoimmunity, superantigen-induced overstimulation, or immunodeficiency. All of these immune disorders are harmful, and some can even be fatal.

In some cases, reactions of the adaptive immune response can damage the host. For example, **hypersensitivity** is an immune response that results in host damage and, in some cases, even host death. Hypersensitivities are grouped according to the antigens and the mechanisms that produce disease. Likewise, exposure to *superantigens*, proteins produced by certain bacteria and viruses that initiate massive inflammatory responses, also causes severe immune reactions that result in host damage. We consider both of these along with immunodeficiency, a condition in which a host's immune response is either absent or insufficient to effectively fight infections.

28.1 Allergy, Hypersensitivity, and Autoimmunity

There are two major types of hypersensitivity: antibody-mediated and cell-mediated. Antibody-mediated, or **immediate hypersensitivity**, is more commonly called *allergy*. Cell-mediated hypersensitivities

also cause allergy-like syndromes but, because of the typically delayed onset of symptoms, are termed **delayed-type hypersensitivity (DTH)**. As discussed in MicrobiologyNow on type 1 diabetes in the opening of this chapter, **autoimmunity** is a harmful immune reaction directed against self antigens. Hypersensitivities are categorized as type I, II, III, or IV based on immune effectors, antigens, and symptoms (**Table 28.1**), and we consider these first.

Immediate Hypersensitivity

Immediate (type I) hypersensitivity occurs because mast cells coated with IgE release substances that either increase or decrease blood pressure or heart rate (vasoactive products) (**Figure 28.1**). Immediate hypersensitivity reactions occur within minutes after exposure to an **allergen**, the antigen that caused the type I hypersensitivity. Depending on the individual and the allergen, immediate hypersensitivity reactions can be mild allergic reactions or can cause a life-threatening reaction called *anaphylaxis*.

Nearly 25% of the population suffers from immediate hypersensitivity allergies to pollens, molds, animal dander, certain foods (strawberries, nuts, and shellfish), insect venoms, dust mites, and other agents. Most allergens enter the body at the surface of mucous membranes, especially those lining the lungs and the gut. Initial exposure to allergens stimulates Th2 cells to produce cytokines that induce B cells to make IgE antibodies. The allergen-specific IgE antibodies bind to IgE receptors on mast cells (**Figure 28.1**). Mast cells are nonmotile granulocytes (◀ Section 26.4) associated with connective tissue adjacent to capillaries throughout the body. With any subsequent exposure to the immunizing allergen, the mast-cell-bound IgE molecules bind the antigen. Cross-linking of IgEs by an antigen triggers *degranulation*—the release of soluble allergic mediators from the mast cells. These mediators cause allergic symptoms within minutes of antigen exposure. After initial sensitization by an allergen, the allergic individual responds to each subsequent reexposure to the allergen.

The principal chemical mediators released from mast cells are *histamine* and *serotonin*, modified amino acids that cause rapid dilation of blood vessels and contraction of smooth muscle, initiating symptoms ranging from mild local discomfort to systemic *anaphylactic shock*. Local symptoms typically include mucus production, rash, sneezing, itchiness, watery eyes, and hives (**Figure 28.2**). Symptoms of anaphylactic shock may include vasodilation (causing a sharp

TABLE 28.1 Hypersensitivity^a

Classification	Description	Immune mechanism	Time of latency	Examples
Type I	Immediate	IgE sensitization of mast cells	Minutes	Reaction to bee venom (sting) Hay fever
Type II	Cytotoxic	IgG interaction with cell surface antigen	Hours	Drug reactions (penicillin)
Type III	Immune complex	IgG interaction with soluble or circulating antigen	Hours	Systemic lupus erythematosus (SLE)
Type IV	Delayed type	Th1 inflammatory cell activation of macrophages	Days (24–48 h)	Poison ivy Tuberculin test

^aAutoimmune diseases may be caused by type II, type III, or type IV reactions.

Figure 28.1 Immediate hypersensitivity. Certain antigens, such as pollens, stimulate IgE production. IgE binds to mast cells by means of a high-affinity surface receptor and arms the mast cell. Antigen cross-links surface IgE, causing release of soluble mediators, including histamine. These mediators produce symptoms ranging from mild allergic symptoms to life-threatening anaphylaxis.

drop in blood pressure) and asthma due to smooth muscle constriction in the lungs.

Severe anaphylaxis is treated immediately with the hormone epinephrine to counter smooth muscle contraction, promote breathing, and increase blood pressure. Less serious allergic symptoms may be treated with *antihistamines*, which are drugs that neutralize histamine, or with anti-inflammatory steroids. Finally, immunization with increasing doses of the allergen (beginning with a tiny amount) can be used to shift antibody production from IgE to IgG and IgA.

Figure 28.2 Hives due to immediate hypersensitivity. The raised, red areas are typical symptoms after contact with allergens that cause immediate hypersensitivity.

The IgG and IgA then interact with the allergen during future exposures and thereby block antigen binding to IgE on sensitized mast cells. This process, called *desensitization*, inhibits IgE production and arrests allergic symptoms.

Delayed-Type Hypersensitivity

Delayed-type (type IV) hypersensitivity (DTH) is cell-mediated hypersensitivity characterized by tissue damage due to inflammation initiated by Th1 cells (Table 28.1). DTH symptoms appear several hours after secondary exposure to the eliciting antigen, with a maximal response usually occurring in 24 to 48 hours. Typical DTH antigens include chemicals that are not normally immunogens but become so when they covalently bind to skin proteins, creating new antigens and eliciting a DTH response. Hypersensitivity to these newly created antigens is known as *contact dermatitis* and results in, for example, skin reactions to poison ivy (Figure 28.3), jewelry, cosmetics, latex, and other chemicals that react with host tissues. Several hours after a second or subsequent exposure to the antigen, the skin feels itchy at the site of contact. Erythema (reddening) and edema (swelling) appear, often with localized tissue destruction in the form of blistering (Figure 28.3) and reach a maximum in several days. The delayed onset and the progress of the inflammatory response are the hallmarks of the DTH reaction. As discussed below, certain self antigens may also elicit DTH responses, resulting in autoimmune disease.

Another example of delayed-type hypersensitivity is the development of protective immunity to the bacterium that causes tuberculosis, *Mycobacterium tuberculosis* (► Section 31.4). The German physician-turned-microbiologist Robert Koch discovered this cellular immune response during his classic studies on tuberculosis over a century ago (◄ Section 1.12). When antigens derived from

Figure 28.3 Delayed-type hypersensitivity. Poison ivy blisters on an arm. The raised rash appears 24–48 hours after exposure to plants of the genus *Rhus* as a result of macrophage activation by Th1 cells sensitized to *Rhus* antigens.

the bacterium were injected subcutaneously into a person previously infected with *M. tuberculosis*, Koch observed that a skin reaction called the *tuberculin reaction* developed within 24–48 hours (**Figure 28.4**). We now know that during this DTH, local Th1 cells stimulated by the introduced *M. tuberculosis* antigens release cytokines that attract and activate large numbers of macrophages, which in turn produce a characteristic local inflammation, including induration (hardening), edema, erythema, pain, and heating of the skin. The activated macrophages then ingest and destroy the invading antigen. Today, the DTH-based tuberculin skin test is used to test for a current or previous infection with *M. tuberculosis* or previous immunization with the tuberculosis vaccine (► Section 29.5).

A number of other infectious diseases due to intracellular pathogens elicit DTH reactions. These include bacterial diseases such as leprosy, brucellosis, and psittacosis; viral diseases such as mumps; and fungal diseases such as coccidioidomycosis, histoplasmosis, and blastomycosis (many of these are covered in Chapters 31–34). Visible, antigen-specific skin responses similar to the tuberculin reaction occur after injection of antigens derived from the pathogens, indicating pathogen exposure and Th1-mediated immunity.

Autoimmune Conditions

As lymphocytes develop, T and B cells that react with self antigens are normally eliminated (◄ Section 27.1). Autoimmune diseases result when these cells are instead activated to produce immune reactions against self proteins (**Table 28.2**). For example, Th1-mediated DTH can cause autoimmune responses directed against self antigens, as in the case of the Th1-mediated response to brain-derived antigens in allergic encephalitis. In type 1 diabetes mellitus (see MicrobiologyNow in the chapter opener), Th1 cells mount an immune response directed to antigens on insulin-producing β cells in the pancreas. The destruction of these cells leads to insulin insufficiency and an inability to control blood sugar levels without an insulin supplement.

In addition to these examples, some autoimmune diseases are caused by **autoantibodies**, antibodies that bind self antigens, many

of which are organ-specific. For example, in *Hashimoto's disease* (hypothyroidism), autoantibodies are made against thyroglobulin, a protein product of the thyroid gland that assists in the synthesis of thyroid hormones. In this disease, antibodies to thyroglobulin bind complement proteins (◄ Section 26.9), leading to local inflammation and the destruction of host cells, the hallmarks of a type II hypersensitivity disease (**Table 28.2**).

Systemic lupus erythematosus (SLE) is an autoimmune disease caused by a type III hypersensitivity. This disease and others like it are caused by autoantibodies directed against soluble, circulating self antigens. In SLE, the antigens include nucleoproteins and even DNA itself. Autoantibodies that bind to soluble proteins produce insoluble immune complexes, and disease symptoms result when these circulating antigen–antibody complexes deposit in different body tissues, such as the kidney, lungs, and spleen. In the tissues, the antibodies bind complement, resulting in inflammation and local, often severe, tissue damage. Type III hypersensitivities are also called *immune complex disorders* (**Table 28.1**).

Treating Autoimmunity

Organ-specific autoimmune diseases are sometimes more easily treated than diseases that affect multiple organs. For example, the product of organ function, such as thyroxine in autoimmune hypothyroidism or insulin in type 1 diabetes, can often be supplied in pure form from another source, such as genetically modified bacteria (◄ Section 12.6 and **Table 12.1**). SLE, rheumatoid arthritis, and other autoimmune diseases that affect multiple organs and sites can often be controlled only by general immunosuppressive therapy, such as the use of steroid drugs. Unfortunately, the immunosuppression associated with these treatments significantly increases the chance of developing infections from opportunistic pathogens.

As an alternative to traditional immunosuppressive treatments, monoclonal antibodies (a single antibody type, ► Section 29.5) have emerged as a promising therapeutic strategy to combat autoimmune diseases. For example, adalimumab (marketed as the drug Humira®) is a monoclonal antibody that neutralizes tumor

Figure 28.4 The tuberculin test and macrophage activation. This tuberculin test shows a positive reaction. Macrophages activated by antigen-specific Th1 cells cause the localized, delayed-type reaction to a tuberculosis antigen, tuberculin, at the site of injection. The raised area of inflammation on the forearm is about 1.5 cm in diameter.

TABLE 28.2 Some autoimmune diseases of humans

Disease	Organ, cell, or molecule affected	Mechanism (hypersensitivity type ^a)
Type 1 diabetes (insulin-dependent diabetes mellitus)	Pancreas	Cell-mediated immunity and autoantibodies against surface and cytoplasmic antigens of beta cells of pancreatic islets (II and IV)
Myasthenia gravis	Skeletal muscle	Autoantibodies against acetylcholine receptors on skeletal muscle (II)
Goodpasture's syndrome	Kidney	Autoantibodies against basement membrane of kidney glomeruli (II)
Rheumatoid arthritis	Cartilage	Autoantibodies against self IgG antibodies, which form complexes deposited in joint tissue, causing inflammation and cartilage destruction (III)
Hashimoto's disease (hypothyroidism)	Thyroid	Autoantibodies to thyroid surface antigens (II)
Male infertility (some cases)	Sperm cells	Autoantibodies agglutinate host sperm cells (II)
Pernicious anemia	Intrinsic factor	Autoantibodies prevent absorption of vitamin B ₁₂ (III)
Systemic lupus erythematosus (SLE)	DNA, cardiolipin, nucleoprotein, blood clotting proteins	Autoantibody response to various cellular constituents results in immune complex formation (III)
Addison's disease	Adrenal glands	Autoantibodies to adrenal cell antigens (II)
Allergic encephalitis	Brain	Cell-mediated response against brain tissue (IV)
Multiple sclerosis	Brain	Cell-mediated and autoantibody response against central nervous system (II and IV)

^aSee Table 28.1.

necrosis factor alpha (TNF- α), an inflammatory cytokine linked to several autoimmune diseases including rheumatoid arthritis, Crohn's disease, and psoriasis. Similarly, the monoclonal antibody belimumab (marketed as the drug Benlysta®) targets B-cell activating factor, a cytokine that stimulates B cell maturation but is overexpressed in SLE patients, causing the persistence of B cells that produce autoantibodies. Other immunotherapeutic strategies to control autoimmunity focus on limiting the proliferation of proinflammatory Th17 cells by stimulating the production of regulatory T (Treg) cells; the latter function as "brakes" of the immune system to limit harmful inflammatory responses (◀ Section 27.8). We explore immunotherapeutic treatments further in Section 28.4.

Heredity often influences the incidence, type, and severity of autoimmune diseases. Many autoimmune diseases correlate strongly with the presence of certain major histocompatibility proteins (◀ Section 27.6). Studies of autoimmune diseases in mice support a genetic link, but the precise conditions necessary for developing autoimmunity may also depend on other factors, such as prior infections, gender, age, and health status. Women, for example, are about ten times more likely to develop SLE than are men. It is thus likely that the balance between a normal immune response and autoimmunity is tipped by a combination of factors in which genetic predisposition plays a central role.

Check Your Understanding

- Discriminate between immediate hypersensitivity and delayed-type hypersensitivity with respect to antigens and immune effectors.
- Provide examples and mechanisms for an antibody-mediated autoimmune disease directed against a specific organ and one that produces circulating immune complexes.

28.2 Superantigens and Immunodeficiency

Extremes in the adaptive immune response, whether overactive or deficient, can have devastating effects on the host. The exotoxins (◀ Sections 25.6 and 25.7) called *superantigens* damage host cells indirectly by subverting the immune system such that T cells and their cytokine products destroy host tissues through an exaggerated immune response. By contrast, some diseases—either genetic or infectious—cause *immunodeficiency*, resulting in increased susceptibility of the host to infectious diseases. We now consider these opposing extremes in the adaptive immune response.

Superantigens

Superantigens are proteins that, upon exposure to the immune system, activate many more T cells than normal and are therefore capable of eliciting an unusually strong immune response. A variety of viruses and bacteria produce superantigens. For example, streptococci and staphylococci, especially certain strains of *Streptococcus pyogenes* and *Staphylococcus aureus*, produce several different extremely potent superantigens in the condition known as *toxic shock syndrome* (Figure 28.5) (▶ Sections 31.2 and 31.9).

Superantigen interaction with TCRs differs from conventional antigen–TCR binding. Ordinarily, foreign antigens presented by MHC proteins, such as those on the surface of an antigen-presenting cell, bind to a TCR at a defined antigen-binding site (◀ Figure 27.18). By contrast, superantigens bind to sites on TCR and MHC proteins that are outside the antigen-specific binding site (Figure 28.6). A superantigen binds to all TCRs that share a common structure, and many different TCRs share the same structure outside the antigen-binding site. Whereas less than 0.01% of all available T cells interact with a conventional foreign antigen in a typical immune response, some superantigens can bind up to 25% of all T cells in the body. These interactions mimic conventional antigen

Figure 28.5 Toxic shock syndrome. This individual has a swollen and bumpy tongue called “strawberry tongue,” a symptom of toxic shock syndrome caused by a *Staphylococcus aureus* superantigen.

presentation and activate large numbers of T cells to grow and divide. As in normal immune responses, the activated T cells produce cytokines that stimulate phagocytes and other immune cells. However, the unusually large cytokine production by the enhanced population of superantigen-activated T cells triggers a widespread cell-mediated response characterized by systemic inflammatory reactions. The resulting fever, diarrhea, vomiting, mucus production, and even systemic shock may be fatal in extreme cases. The clinical symptoms of superantigen shock are indistinguishable from those of septic shock, a condition in which a bacterial infection has spread throughout the body (◀ Section 26.8).

One of the most common superantigen diseases is *Staphylococcus aureus* food poisoning, characterized by fever, vomiting, and diarrhea, and caused by one of several superantigen staphylococcal enterotoxins (▶ Section 33.8). *S. aureus* also produces the superantigen responsible for *toxic shock syndrome* (Figure 28.5), and *Streptococcus pyogenes* produces *erythrogenic toxin*, the superantigen responsible for scarlet fever (▶ Section 31.2).

Immunodeficiency

Active adaptive immunity is critical for infectious disease resistance. We know this because of problems caused by genetic defects and diseases that affect the adaptive immune system. For example, animals that cannot produce antibodies because of genetic defects in their B cells acquire serious infections from extracellular pathogens, especially bacteria. In addition, animals with genetic defects that prevent development of T cells suffer from recurrent infections with viruses and other intracellular pathogens.

Severe combined immune deficiency syndrome (SCID) is a genetic disorder that prevents proper formation of B and T cells. Individuals with SCID essentially have no effective adaptive immunity. A lack of proper T cell function results in a deficiency of cell-mediated immunity and indirectly causes a loss of antibody-mediated immunity because B cell activation against most antigens requires functional Th cells. Unless SCID patients receive supportive therapy, such

as a bone marrow transplant and antibiotic treatments, SCID eventually causes death from multiple recurrent infections. The transplantation of compatible bone marrow tissue provides the afflicted individual with hematopoietic stem cells (◀ Sections 26.3 and 26.4) free of the genetic defects that cause SCID.

Gene therapy has also shown promise as a curative treatment option for some forms of SCID. In this procedure, defective genes in hematopoietic stem cells are replaced through a transduction process using viral vectors (◀ Section 9.7). As with bone marrow transplantation, successful gene therapy restores function of the adaptive immune system. However, using viral vectors—even genetically engineered vectors—can be risky because of secondary effects that the viruses may have, such as activating host genes that initiate tumor growth. Because of this, powerful new tools for genome editing (◀ Section 12.13) that do not require viral vectors are being developed, and thus safe genetic therapies for SCID may be on the horizon.

In some cases, immunodeficiency is not the result of a genetic disorder but rather is caused by microbial infection. The best-studied example of this is the loss of the adaptive immune response due to *acquired immunodeficiency syndrome* (AIDS). Human immunodeficiency virus (HIV) infects host cells that express the CD4 cell surface protein. The virus initially infects macrophages but later attacks and replicates primarily in Th cells (Figure 28.7). Once infected, Th cells cease dividing and eventually die. Therefore, in untreated cases, HIV infection causes a gradual depletion of Th cells, resulting in a lack of effective immunity and the eventual onset of AIDS (▶ Section 31.15 and Figure 31.45).

In most AIDS patients, the actual cause of death is not directly attributed to HIV but rather to secondary microbial infections caused by *opportunistic pathogens* (◀ Section 25.4). Many of these infections are caused by fungal, bacterial, and viral pathogens that only rarely cause serious disease symptoms in individuals that have

Figure 28.6 Superantigens. Superantigens bind to conserved regions of both the MHC and TCR proteins at positions outside the normal binding site. Superantigens interact with large numbers of T cells, causing large-scale T cell activation, cytokine release, and systemic inflammation.

Figure 28.7 HIV infection of a Th cell. Colorized scanning electron micrograph of HIV virions (yellow) attacking a Th cell (red).

a fully functional immune system. The deficiency of adaptive immunity in AIDS patients allows these opportunistic pathogens to colonize and invade body tissues, eventually leading to death. We discuss the pathogenicity, symptoms, treatment, and other aspects of HIV/AIDS in more detail in Chapter 31.

Check Your Understanding

- Describe the binding site for superantigens on T cells and antigen-presenting cells. How does this correlate to the activation of a much larger population of T cells than normal upon exposure to superantigens?
- Compare and contrast the immunodeficiency observed in SCID patients to that of AIDS patients. What cell types are affected by each condition?
- In the absence of treatment, what is the prognosis for individuals afflicted with SCID and AIDS?

II • Vaccines and Immunotherapy

Vaccines are indispensable preventive tools to train the immune system to recognize and attack specific pathogens upon exposure. Immunotherapy is a treatment option that uses therapeutic agents to either activate or suppress immune responses to specific diseases, including cancer.

As we have seen, malfunctions of the immune system can either contribute to disease signs and symptoms (hypersensitivity and autoimmunity) or result in a failure to contain them (immunodeficiency). Here we move on to discuss ways in which attributes of the immune system can be harnessed to develop tools and strategies to both *prevent* and *treat* diseases.

28.3 Vaccination Against Infectious Diseases

A major means of disease prevention is **vaccination (immunization)**, in which deliberate exposure to an antigen triggers an adaptive immune response intended to protect an individual against future infection by a pathogen. The immunogen used to induce this artificial active immunity is called a **vaccine**. A summary of major diseases for which vaccines are available for human use is given in **Table 28.3**.

TABLE 28.3 Vaccines for infectious diseases in humans	
Bacterial diseases	Type of vaccine used
Anthrax	Toxoid
Cholera	Killed cells or cell extract (<i>Vibrio cholerae</i>)
Diphtheria	Toxoid
<i>Haemophilus influenzae</i> type b meningitis	Conjugated vaccine (polysaccharide of <i>Haemophilus influenzae</i> type b conjugated to protein)
Meningitis	Purified polysaccharide from <i>Neisseria meningitidis</i>
Paratyphoid fever	Killed bacteria (<i>Salmonella enterica</i> [paratyphi])
Pertussis	Killed bacteria (<i>Bordetella pertussis</i>) or acellular proteins
Plague	Killed cells or cell extract (<i>Yersinia pestis</i>)
Pneumonia (bacterial)	Purified polysaccharide from <i>Streptococcus pneumoniae</i> or polysaccharide–toxoid conjugate
Tetanus	Toxoid
Tuberculosis	Attenuated strain of <i>Mycobacterium tuberculosis</i>
Typhoid fever	Killed bacteria (<i>Salmonella enterica</i> [typhi])
Typhus	Killed bacteria (<i>Rickettsia prowazekii</i>)
Viral diseases	Type of vaccine used
Hepatitis A	Recombinant DNA vaccine
Hepatitis B	Recombinant DNA vaccine or inactivated virus
Human papillomavirus (HPV)	Recombinant DNA vaccine
Influenza (seasonal or H1N1)	Inactivated or attenuated virus
Japanese encephalitis	Inactivated virus
Measles and mumps	Attenuated virus
Polio	Attenuated virus (Sabin) or inactivated virus (Salk)
Rabies	Inactivated virus (human) or attenuated virus (animal)
Rotavirus	Attenuated virus
Rubella	Attenuated virus
Smallpox and monkeypox	Cross-reacting virus (vaccinia)
Varicella (chicken pox/shingles)	Attenuated virus
Yellow fever	Attenuated virus

The Nature of Vaccines

Infants are immune to many common infectious diseases during the first several months of life because they acquire natural passive immunity from maternal antibodies transferred across the placenta and in breast milk (◀ Section 24.8). However, it is recommended that infants be immunized against key infectious diseases as soon as possible so that their own active immunity can replace the temporary maternal passive immunity (Figure 28.8). As discussed in Section 27.3, a single exposure to antigen does not lead to a high antibody titer. After an initial immunization, a series of “booster” immunizations are given to produce a secondary response and a high antibody titer.

It is well established that the introduction of effective vaccines into a population has reduced the incidence of formerly epidemic childhood diseases such as measles and mumps (▶ Section 31.6) and has eliminated smallpox altogether (▶ Section 30.5). However, lifelong immunity is rarely achieved by vaccination because the

immune cells and antibodies generated by immunization gradually disappear from the body. In the absence of environmental antigenic stimulation, the length of effective immunity varies considerably with different vaccines. For example, the tetanus toxoid vaccine provides effective immunity for ten years, but immunity induced by inactivated influenza virus vaccine generally disappears within a year or two (the reasons for this short-term immunity in the case of influenza are considered in Section 31.8).

To minimize the risk of infection or other adverse reactions, pathogens or pathogen products used in vaccines must be made harmless. To achieve this, many vaccines consist of pathogens killed either by heat treatment or by chemical agents. For example, formaldehyde is used to inactivate polio virions for preparation of the Salk polio vaccine. In addition, many exotoxins can be chemically modified to create a *toxoid*, a molecule that retains its antigenicity but is no longer toxic. Toxoid vaccines, such as the vaccine for *Clostridium tetani* (the causative agent of tetanus, ▶ Section 32.9), safely induce long-term protective immunity against the exotoxin.

Immunization with intact pathogens is usually more effective than immunization with dead or inactivated material. It is often possible to isolate *attenuated strains* of pathogens—those that have lost their virulence but still retain the immunizing antigens (◀ Figure 25.10). However, because attenuated strains of pathogens are still viable, some individuals may inadvertently acquire active disease from the vaccination. Nevertheless, attenuated vaccines are widely used because they tend to provide long-lasting immunity and a strong secondary booster response. By contrast, killed virus vaccines generally provide short-lived immune responses with less long-term memory.

Most bacterial vaccines are composed of key cellular antigens in an inactivated form, such as the toxoids that protect against tetanus and diphtheria. Inactivated bacterial vaccines induce antibody-mediated protection without exposing recipients to the risk of infection. However, variability in primary and secondary responses with each vaccine and individual make periodic reimmunization necessary to establish and maintain immunity.

Synthetic and Genetically Engineered Vaccines

An alternative approach to vaccine development is to deploy the tools of genetic engineering (Chapter 12) to produce *synthetic peptides*. To make such a vaccine, a genetic engineer can synthesize a peptide that corresponds to an antigen from an infectious agent. For example, the toxin from the foot-and-mouth disease virus, an important animal pathogen, must be modified from its native form to render it harmless for use as a vaccine. The toxin contains a peptide of 20 amino acids that is an important antigenic determinant in the protein, but the peptide is too small to be an effective vaccine by itself. However, genetic engineers attached the small peptide to a larger, innocuous protein that acts as a carrier molecule, creating a *conjugate vaccine* against foot-and-mouth disease virus. This strategy has great promise for creating vaccines for a number of other pathogens as well, especially because the complete genomic sequences of many pathogens are now known, and this provides the insight necessary to pinpoint the most likely antigenic molecules.

Two widely available conjugate vaccines couple extracted bacterial polysaccharides, which are poorly immunogenic by themselves, to a protein toxoid, thereby inducing a more robust immune response

Immunizations against bacteria	Immunizations against viruses
<i>Haemophilus influenzae</i> type B (Hib)	Hepatitis A virus
Meningococcal (<i>Neisseria meningitidis</i>)	Hepatitis B virus
Pneumococcal (<i>Streptococcus pneumoniae</i>)	Human papillomavirus (HPV)
Tetanus, diphtheria, pertussis (DTaP, Tdap)	Influenza virus
	Inactivated poliovirus (IPV)

	Rotavirus
	Varicella virus (chicken pox)

Figure 28.8 Immunization recommendations for infants and children in the United States. The U.S. Centers for Disease Control and Prevention website (<http://www.cdc.gov>) has recommendations for timing and dose of immunizations for all age groups and for special populations, such as international travelers, women of childbearing age, and those with immunodeficiency or chronic disease.

with better immune memory than injection of the polysaccharide antigen alone. The first of these is a pneumococcal vaccine that pairs diphtheria toxoid to polysaccharide capsule antigens derived from pathogenic strains of *Streptococcus pneumoniae*, the causative agent of bacterial pneumonia (► Section 31.2) (Figure 28.9). The second is the *Haemophilus influenzae* type b (Hib) vaccine, which couples Hib polysaccharide to tetanus toxoid. The conjugation of polysaccharide antigens to protein toxoids efficiently activates Th2 cells, resulting in a strong immune response that confers immune memory.

Genomic information is particularly useful for making viral vaccines. Genes that encode antigens from virtually any virus can be cloned into the vaccinia virus genome and expressed (◄ Section 12.8). Inoculation with the antigen-producing vaccinia virus can induce immunity to the product of the cloned gene. Such a preparation is called a *recombinant-vector vaccine*, an example of which is the recombinant vaccinia–rabies vaccine used in animals. A second immunization strategy uses proteins made from cloned DNA as immunogens. After a pathogen gene is cloned and expressed in a suitable microbial host, the pathogen protein is harvested and used to produce a *recombinant-antigen vaccine*. For example, the current vaccine for hepatitis B virus (► Section 31.11) is a major hepatitis B surface protein antigen (HbsAg) expressed in genetically modified yeast cells. Similarly, a vaccine effective against human papilloma-virus (HPV, ► Section 31.14) is also a recombinant-antigen vaccine made in yeast cells.

Nucleic Acid Vaccines and Plant-Based Vaccines

A novel vaccine delivery method is seen with the *DNA vaccines*, vaccines in which the antigen(s) of interest are not injected into the

animal but are actually *synthesized* by the animal. DNA vaccines are bacterial plasmids that contain cloned DNA that encodes the antigen of interest. Typically, the vaccine is injected intramuscularly into a host animal. Once host cells take up the plasmid, the DNA is transcribed and translated to produce immunogenic proteins, triggering a conventional immune response of activated T cells and antibodies directed to the protein encoded by the cloned DNA. A major advantage of DNA vaccines is that, because only a single pathogen gene is cloned into the plasmid and administered to the host, there is no chance of an infection, as there might be with an attenuated vaccine.

A second nucleic acid–based vaccine methodology that has shown promise as an alternative to conventional methods is *mRNA vaccines*. In this approach, RNA that encodes an antigen of interest and has been engineered to resemble a fully processed, mature mRNA suitable for translation in eukaryotic cells (◄ Section 6.6) is administered to the animal, and production of the protein by host cells produces an adaptive immune response to the antigen. As with DNA vaccines, there is no risk of infection from mRNA vaccines, but in addition, the short half-life of mRNA allows for greater control of protein expression and immunogenicity. Early challenges associated with instability and inefficient *in vivo* delivery of mRNA vaccines have largely been overcome, and therefore this vaccine platform may be of great importance for future disease control and prevention.

Lastly, a novel variation of the recombinant-antigen vaccine described above uses fast-growing plants as the transgenic host to produce *plant-based vaccines*. In this method, the pathogen-derived target gene is transferred to the plant using the plant pathogen *Agrobacterium tumefaciens* as a bacterial vector (◄ Sections 12.7 and 23.6).

Figure 28.9 Conjugate vaccines. Conjugate vaccines, such as *Streptococcus pneumoniae* (pneumococcus) polysaccharide covalently linked to diphtheria toxoid (shown) or *Haemophilus influenzae* type B (Hib) polysaccharide coupled to tetanus toxoid provide effective immunity to polysaccharide antigens, which are poor immunogens in the absence of protein carriers.

Following plant infection by *A. tumefaciens*, recombinant proteins are extracted from the plants and purified to produce *virus-like particles* (VLPs), lipid bilayer constructs embedded with pathogen-specific protein antigens. VLPs produce a strong immune response, but because they lack the genetic material of the native pathogen, they cannot replicate or cause infection. Promising VLP vaccines are in development for a wide variety of viral pathogens, including rotavirus, norovirus, West Nile virus, hepatitis B virus, and pandemic influenza.

- Compare and contrast live attenuated vaccines, inactivated vaccines, and toxoids. Which of these has the greatest potential to cause active disease in the recipient? Which typically provides the longest-lasting immunity?
- Identify the advantages of alternative immunization strategies as compared to traditional immunization procedures.

28.4 Immunotherapy

As we have seen, the immune system can be manipulated to provide protection against future pathogen exposures through vaccination strategies. In addition to this, **immunotherapy** is a burgeoning field in clinical medicine that seeks to harness cells and other components of the immune system to fight or prevent diseases, including various forms of cancer. Diagnostic tests for cancer typically begin with either a tissue biopsy for solid tumors or a blood sample for hematological cancers or circulating cancer cells. Key immunotherapeutic approaches currently in development to combat cancer include *anticancer vaccination*, the use of *checkpoint inhibitors* to stimulate the antitumor immune response, and *adoptive T cell transfer*, an encouraging approach that optimizes T cell activity against a variety of cancers (Figure 28.10).

Anticancer Vaccines

Attempts to develop anticancer vaccines have historically been ineffective in practice, but due to recent advances in molecular immunology, interest is once again growing in this area. Although a universal vaccine to protect against all cancer is unlikely to be realized considering the many different types of cancer that exist, immunotherapeutic vaccines are currently in development for certain cancers, including melanoma, pancreatic cancer, and glioblastoma, an aggressive brain cancer with an otherwise poor prognosis.

Anticancer vaccines can be either *prophylactic* (preventive) or *therapeutic*. Rather than preventing cancer directly, prophylactic vaccines target oncogenic pathogens, such as human papillomavirus, the causative agent of most cervical and anal cancers, and hepatitis B virus, which can cause liver cancer. Therapeutic anticancer vaccines are designed to stimulate the body's natural immune response to cancer cells. Advances in genomics, including digital innovations that allow for detailed data analyses, have led to *personalized cancer vaccines*. By mapping specific oncogenic mutations in extracted tumor cells, a patient's dendritic cells can be sensitized to new antigens (called "neoantigens") that appear on the transformed tumor

cells, resulting in a potent anticancer response mediated by activated T cells (Figure 28.10).

Checkpoint Inhibitors

The tumor microenvironment has been shown to be immunosuppressive, which is an obstacle to cancer treatment. This is largely due to the production and activity of immune checkpoint proteins, including programmed cell death protein-1 (PD-1) and cytotoxic T-lymphocyte-associated protein-4 (CTLA-4), which function to suppress the adaptive immune response. PD-1 and CTLA-4 inhibit T cell activation by regulating the TCR costimulatory protein CD28 and competing with CD28 for protein B7 on APCs, respectively (◀ Figure 27.20). Normally, these functions prevent uncontrolled inflammation and autoimmune responses, but cancer cells exploit these checkpoint proteins to suppress immunity and evade anticancer effector cells.

The goal of checkpoint inhibitor therapy (also called *checkpoint blockade*), therefore, is to prevent neutralization of cytotoxic T cells and stimulate their tumoricidal effector activity. The most successful checkpoint inhibitors are monoclonal antibody (mAb)-based drugs (▶ Section 29.5), such as pembrolizumab (marketed as Keytruda®), that target PD-1 on T cells (or its ligand PD-L1 on cancer cells) in solid tumors and block inhibition of the antitumor immune response (Figure 28.10). Checkpoint inhibitors are often combined with steroids or other immunity-modulating drugs to boost their efficiency, but the safety and efficacy of these combined treatment strategies are still being assessed in clinical trials. Recall from Section 28.1 that mAbs are also used to treat autoimmune disorders, and therefore it is important to note that, depending on their activity, these drugs may be used to either suppress (to combat autoimmunity) or stimulate (to treat cancer) the immune response.

Adoptive T Cell Transfer

Adoptive T cell transfer (ACT) is a novel type of cancer immunotherapy that focuses on harnessing the tumor-targeting abilities of T cells. Two main approaches have been developed for ACT therapy: tumor-infiltrating lymphocytes (TILs) and chimeric antigen receptor (CAR) T cells (Figure 28.10).

TILs are effector T cells having natural anticancer activity that are extracted from tumors, propagated in the laboratory and then infused back into the patient to amplify the immune response against the cancer cells. TIL therapy has proven especially effective in treating melanoma—a dangerous and often metastasizing (spreading) form of cancer—and clinical trials using TILs against this and other forms of cancer, including ovarian, renal cell, and nasopharyngeal cancers, are under way.

CAR T cell therapy is a form of ACT that employs genetically engineered T cells to treat various cancers, especially B cell malignancies such as leukemia and lymphoma. CARs are engineered receptors that are an amalgam of components from TCRs, costimulatory molecules such as CD28, and the antigen-binding domains of antibodies (◀ Figure 27.11) specific to tumor neoantigens (Figure 28.10). The synthesis of CAR T cells is complex and, like TIL therapy, requires extraction of the patient's T cells for laboratory

Figure 28.10 Overview of cancer immunotherapy. Anticancer vaccines can potentially be designed from properties of extracted tumor cells or the patient's dendritic cells. Checkpoint blockade uses monoclonal antibodies to neutralize immunosuppressive components, such as PD-1/PD-L1 and CTLA-4, in the tumor microenvironment. CARs are genetically engineered receptors that reprogram cytotoxic T cells to recognize and be directly activated by tumor-specific antigens. CAR, chimeric antigen receptor; mAb, monoclonal antibody; TIL, tumor-infiltrating lymphocyte.

manipulation. The manipulation includes introducing a CAR-containing viral vector and clonal expansion of the transgenic T cells before infusion back into the patient. Essentially, CAR T cells are customized to recognize tumor-specific antigens and kill cancer cells *even in the absence of MHC antigen presentation* (◀ Section 27.5). The latter is possible because the antigen-binding domain of CARs is of

immunoglobulin origin rather than TCR origin.

Although treatments such as checkpoint inhibitors and CAR T cells are undeniably powerful immunotherapeutic tools, these technologies are also accompanied by several unresolved challenges, including the requirement to overcome immunosuppressive tumor microenvironments and side effects such as neurologic toxicity and excessive proinflammatory cytokine release. In addition, reactions to the same therapies can vary widely in different individuals, a response that could be the result of person-to-person differences in our gut microbiota (Chapter 24), a consideration we turn to now (Figure 28.11).

Immunotherapeutic Efficacy and the Gut Microbiome

The composition of each person's gut microbiota plays a significant role in the efficacy of a given immunotherapeutic treatment. For example, studies in mice have shown that administering *Bifidobacterium* as an oral probiotic produces an antitumor effect, and the use of PD-1/PD-L1 checkpoint inhibitors in addition to the probiotic can eliminate tumor growth entirely. Subsequent studies revealed that the abundance of the bacterium *Bifidobacterium* is particularly high in feces of melanoma patients that respond favorably to PD-1/PD-L1 blockade, and transplanting samples of the feces into germ-free mice (fecal transplant, ▶ Sections 24.9 and 24.11) improved the anticancer

activity of checkpoint inhibitors and CD8 T cells in the mice (Figure 28.11). Using data from mouse studies as proof-of-concept, clinical trials are now under way to determine whether fecal transplants from patients who respond favorably to PD-1 checkpoint inhibitor therapy into those who do not respond to the treatment can ameliorate the effect of checkpoint blockade in nonresponders.

antibacterial
agents

Figure 28.11 Immunotherapy and the gut microbiome. Checkpoint blockade responders tend to have high abundance of *Bifidobacterium*, *Akkermansia*, and *Faecalibacterium* spp. in their gut microbiota, whereas nonresponders do not. A fecal transplant from responders into germ-free mice expressing tumors results in increased efficacy of checkpoint inhibition and tumor reduction. Fecal transplants from nonresponders confers no antitumor effect on mice.

The mechanism responsible for the beneficial effect of the transplants has been linked to the release of immune-stimulating cytokines by gut-associated lymphoid tissue upon interaction with the beneficial bacteria. The goal now is to streamline the procedure and increase its reproducibility by determining as precisely as possible which microbes are conferring the beneficial effect and formulating a probiotic suspension of just those organisms. In addition to *Bifidobacterium*, research has focused on species of *Bacteroides*, *Faecalibacterium*, and *Akkermansia* (Figure 28.11) and species of the family *Ruminococcaceae*. Knowledge of the major contributors will minimize potential problems with quality control, as well as the risk of inadvertent transfer of pathogens or immunosuppressive strains in fecal transplants, both of which could undermine the benefits of the treatment.

Check Your Understanding

- How do checkpoint inhibitors stimulate the immune response in the tumor microenvironment? How do chimeric antigen receptors (CARs) differ from T cell receptors (TCRs)?
- Explain how the composition of the gut microbiome may influence the efficacy of cancer immunotherapy. What evidence do we have for this phenomenon?

III • Drug Treatments for Infectious Diseases

Antimicrobial drugs kill or inhibit microorganisms by a variety of mechanisms and are of immense importance in clinical medicine. However, antimicrobial drug resistance is an escalating threat and a major impediment to the treatment of certain infections.

28.5 Antibacterial Drugs

In cases where immunization is either not an option or fails to prevent disease, antimicrobial drug therapy is the primary weapon against infections. Antimicrobial drugs either kill or inhibit the growth of microorganisms in the host (in vivo) and are classified based on their molecular structure, mechanism of action (Figure 28.12), and spectrum of antimicrobial activity. **Antibiotics** are antimicrobial agents that are produced naturally by certain microorganisms, typically species of *Bacteria* or fungi. In addition to natural antibiotics, many other drugs are produced synthetically. Regardless of their origin, it is desirable that antimicrobial drugs exhibit **selective toxicity**—they inhibit or kill pathogens without adversely affecting the host. Although thousands of antibiotics are known, fewer than 1% are clinically useful, often because of problems with host toxicity or lack of uptake by host cells.

The susceptibility of individual microbes to different antimicrobial agents varies significantly. For example, gram-positive *Bacteria* are often sensitive to natural penicillin, whereas gram-negative *Bacteria* are generally resistant; thus, natural penicillin exhibits a relatively **narrow spectrum** of activity. By contrast, antibiotics that exhibit **broad-spectrum** activity, such as tetracycline, are generally effective against both groups. Although broad-spectrum antibiotics often find wider medical use than narrow-spectrum antibiotics, antibiotics with a limited spectrum of activity may be quite useful against certain pathogens, especially those that fail to respond to other antibiotics. A good example is vancomycin, a narrow-spectrum antibiotic that is an effective bactericidal agent for penicillin-resistant, gram-positive *Bacteria*, including certain enterococci, staphylococci, and clostridia.

Important targets of antibiotics in *Bacteria* include the cell wall, ribosomes, enzymes that facilitate nucleic acid synthesis or catalyze metabolic processes, and the cytoplasmic membrane (Figure 28.12). We provided an overview of antibiotic targets in Section 8.11 and now consider the mechanisms of drug activity in further detail.

The Bacterial Cell Wall as a Drug Target

Worldwide, an estimated 100,000 metric tons of antibacterial drugs are manufactured and used annually (Figure 28.13a), and the vast majority of these target the bacterial cell wall. **β -lactam antibiotics**, which include penicillins and cephalosporins, inhibit cell wall synthesis and account for nearly two-thirds of all antibiotics produced and used worldwide (Figure 28.13b). These antibiotics share a characteristic structural component, the **β -lactam ring** (Figure 28.14), and historically have been some of the most effective weapons against many different types of bacterial infections.

Figure 28.12 Mechanisms of action of major antibacterial agents. Agents are classified according to their target structures in the bacterial cell. THF, tetrahydrofolate; DHF, dihydrofolate; PABA, *p*-aminobenzoic acid.

The first β -lactam antibiotic ever characterized was penicillin G, isolated from the fungus *Penicillium chrysogenum* in 1929 by Alexander Fleming. This new drug was dramatically effective for controlling staphylococcal and pneumococcal infections and was more effective for treating streptococcal infections than the synthetic sulfa drugs, discussed later in this section. Penicillin and other β -lactam antibiotics interfere with an important feature of bacterial cell wall synthesis called *transpeptidation*, the reaction catalyzed by transpeptidases that results in the cross-linking of two glycan-linked peptide chains

(◀ Sections 2.3 and 8.5). Because peptidoglycan synthesis mechanisms are unique to *Bacteria*, the β -lactam antibiotics are highly selective and nontoxic to host cells.

Penicillin G is active primarily against gram-positive *Bacteria* because gram-negative *Bacteria* are impermeable to the antibiotic. However, chemical modification of the *N*-acyl group of penicillin G produces *semisynthetic* penicillins, such as ampicillin and carbenicillin, which have broader activity and are effective against certain gram-negative *Bacteria* (Figure 28.14). The structural differences in these semisynthetic penicillins allow them to be transported across the gram-negative outer membrane (◀ Section 2.4), where they inhibit cell wall synthesis. Penicillin G is also sensitive to β -lactamases, enzymes that destroy β -lactam antibiotics and are produced by many penicillin-resistant *Bacteria* (see Section 28.7). Oxacillin and methicillin are widely used β -lactamase-resistant semisynthetic penicillins (Figure 28.14).

Cephalosporins, produced by species of the fungus *Cephalosporium*, differ structurally from the penicillins. They retain the β -lactam ring but have a six-member dihydrothiazine ring joined to it instead of the five-member thiazolidine ring of penicillins (Table 28.4 and Figure 28.14). The cephalosporins have the same mode of action as the penicillins; they bind irreversibly to transpeptidases and prevent the cross-linking of peptidoglycan. Clinically important cephalosporins are semisynthetic antibiotics with a broader spectrum of activity than the penicillins. In addition, cephalosporins are typically more resistant to β -lactamases. For example, ceftriaxone (Table 28.4) is highly resistant to β -lactamases and has replaced penicillin for treatment of gonorrhea because many *Neisseria gonorrhoeae* strains have become resistant to penicillin (see Section 28.7).

Some antimicrobial drugs mimic *growth factors*, organic nutrients obtained from an organism's environment that are required by the organism for growth and survival (◀ Section 3.1). A **growth factor analog** is a synthetic compound that chemically resembles a growth

Figure 28.13 Annual worldwide production and use of antibiotics. (a) An estimated 100,000 metric tons of antimicrobial agents are manufactured worldwide per year, and nearly two-thirds of this amount is used in an agricultural context. (b) By far, the β -lactam antibiotics (penicillins and cephalosporins) constitute the most important and widely used class of antibiotic. "Other" includes trimethoprim combinations, tetracyclines, chloramphenicol, aminoglycosides, and all other antimicrobial drug classes. Data are from the Center for Disease Dynamics, Economics, and Policy, Washington, DC.

Figure 28.14 Structure of selected penicillins. The red arrow (top panel) indicates the site within the β -lactam ring cleaved by most β -lactamases, enzymes that destroy penicillin and other β -lactam antibiotics. Although the *N*-acyl group (blue shading) varies among different penicillin drugs, all penicillins have a common nucleus consisting of a β -lactam ring and a thiazolidine ring. Whereas penicillin G must be injected, most acid-stable penicillins can be administered orally (carbenicillin is an exception).

factor, but whose subtle structural differences prevent the analog from functioning as a growth factor in the cell, thereby disrupting cell metabolism. Isoniazid (Table 28.4) is an important growth factor analog with a very narrow spectrum of activity. Effective against mycobacteria only, isoniazid is an analog of nicotinamide, a vitamin required for mycolic acid synthesis, which is, in turn, required to construct the mycobacterial cell wall. Isoniazid is one of the most effective drugs for treatment of tuberculosis (► Section 31.4), but isoniazid resistance in strains of *Mycobacterium tuberculosis* is increasing.

Protein Synthesis as a Drug Target

Some antibiotics inhibit bacterial pathogens by disrupting protein synthesis (translation), often through interactions with the ribosome that may include binding to ribosomal RNA (rRNA) (Figure 28.12). Most of these drugs target bacterial (70S) ribosomes only and, therefore, have no effect on the structurally distinct, cytoplasmic ribosomes of eukaryotic cells. However, because mitochondria also contain 70S ribosomes (◄ Section 13.4), many antibiotics that inhibit protein synthesis in *Bacteria* also potentially inhibit mitochondrial protein synthesis in eukaryotic cells. Nevertheless, these

drugs are still medically useful because 70S ribosomes in organelles are affected only at higher concentrations than are used for antimicrobial therapy.

The **aminoglycosides** are antibiotics that inhibit translation by targeting the 30S (small) subunit of the ribosome. Aminoglycosides contain amino sugars linked by glycosidic bonds, and clinically useful examples include streptomycin (produced by the bacterium *Streptomyces griseus*), kanamycin (Table 28.4), neomycin, and gentamicin. These broad-spectrum antibiotics are useful for treating infections caused by gram-negative *Bacteria*, but because of host toxicity effects that include kidney and hearing damage, aminoglycoside use has decreased since the development of the semisynthetic penicillins and tetracyclines. With the exception of gentamicin, which is routinely used to combat *Pseudomonas* infections, and neomycin, which is used in topical antibiotic ointments, aminoglycosides are generally administered only when other antibiotics fail.

Like the aminoglycoside antibiotics, **tetracyclines** interfere with the function of the 30S subunit of the ribosome. Tetracyclines are broad-spectrum antibiotics produced by several species of *Streptomyces*, and they inhibit most clinically relevant gram-positive and gram-negative *Bacteria*. The basic structure of tetracycline consists of a naphthacene ring system (Table 28.4), and side-chain substitutions (either natural or synthetic) to the various rings form new tetracycline analogs. Physicians are cautioned against the administration of tetracyclines to pregnant women and to young children because these antibiotics bind calcium in bones and teeth, weakening them and causing permanent staining of the latter (Figure 28.15). Tetracyclines are widely used in veterinary medicine, though, and in some countries, they are used routinely in healthy animals as nutritional supplements to suppress the growth of pathogens in poultry and swine, a practice that strongly selects for antibiotic resistance (◄ Section 8.11).

Macrolide antibiotics inhibit translation by targeting the 50S (large) subunit of the bacterial ribosome. Their basic structure contains a lactone ring bonded to sugars (as in erythromycin in Table 28.4), and variations in these constituents result in a diversity of macrolide antibiotics. Macrolides account for about 12% of global antibiotic production (Figure 28.13) and include, for example, erythromycin (produced by *Streptomyces erythreus*), clarithromycin, and azithromycin. The partial inhibition of protein synthesis by erythromycin, in particular, leads to preferential translation of some proteins and restricts translation of others, resulting in an imbalance in the proteome and potentially disrupting metabolic functions at all levels. Often used clinically in patients allergic to penicillin or other β -lactam antibiotics, erythromycin is particularly useful for treating legionellosis (► Section 33.4).

Nucleic Acid Synthesis as a Drug Target

The **quinolones** are synthetic antibacterial compounds that disrupt bacterial metabolism by interfering with DNA gyrase, thus preventing the supercoiling and packaging of DNA in the bacterial cell (◄ Section 6.1). Because DNA gyrase is found in all *Bacteria*, quinolones are effective for treating both gram-positive and gram-negative bacterial infections. *Fluoroquinolones*, such as ciprofloxacin (Table 28.4), are fluorinated derivatives of quinolones that are routinely used to treat urinary tract infections and have been widely

used in the beef and poultry industries for prevention and treatment of respiratory diseases in animals. Ciprofloxacin is also the drug of choice for treating anthrax because some strains of *Bacillus anthracis*, the causative agent of anthrax (► Section 32.8), are resistant to penicillin. The fluoroquinolone moxifloxacin is effective for treatment of tuberculosis; in combination with other anti-tuberculosis drugs, moxifloxacin may significantly reduce treatment time, a major problem with isoniazid-based treatments. However, in some individuals the use of fluoroquinolones has been accompanied by serious side effects, including tendon and organ damage and neurotoxicity, although why these occur is not well understood.

Some antibiotics disrupt transcription by inhibiting RNA synthesis (Figure 28.12). For example, rifamycins, such as *rifampin* (Table 28.4), inhibit RNA synthesis by binding to the β -subunit of RNA polymerase in *Bacteria*. Rifampin, often used in concert with isoniazid for treatment of tuberculosis, has the odd side effect of causing body secretions, including tears, urine, and sweat, to turn reddish-orange (Figure 28.16). *Actinomycin* inhibits RNA synthesis by combining with DNA and blocking RNA elongation. This agent binds most strongly to DNA at guanine–cytosine base pairs, fitting into the major groove in the double strand where RNA is synthesized.

Other Antibacterial Drug Targets

Like isoniazids, **sulfa drugs** (also called *sulfonamides*) are synthetic growth factor analogs. However, instead of affecting the cell wall, sulfa drugs block a key biosynthetic pathway in *Bacteria*. Sulfanilamide (Table 28.4), the simplest sulfa drug, is an analog of *p*-aminobenzoic acid (PABA), which is a component of the vitamin folic acid, a nucleic acid precursor. By mimicking PABA, sulfanilamide blocks the synthesis of folic acid, thereby inhibiting nucleic acid synthesis. Sulfanilamide is selectively toxic because bacteria synthesize their own folic acid, unlike humans and most animals, which obtain folic acid from their diet. Antimicrobial therapy with sulfamethoxazole (a sulfa drug) plus trimethoprim, a related folic acid synthesis competitor, is highly effective because the drug combination blocks two sequential steps in the folic acid synthesis pathway (Figure 28.12); resistance to this drug combination therefore requires two mutations in genes of the same pathway, a relatively rare event. However, resistance to sulfonamides is increasing as many formerly susceptible pathogens develop the ability to import folic acid from their environment.

Some antibiotics have atypical structures or targets. For example, the antibiotic *daptomycin* (Table 28.4) is produced by a species of *Streptomyces* and is a cyclic lipopeptide with a unique mode of

action. Used mainly to treat infections by gram-positive *Bacteria*, including pathogenic streptococci and staphylococci, daptomycin binds specifically to bacterial cytoplasmic membranes, forms a pore, and induces rapid depolarization of the membrane. The depolarized cell quickly loses its ability to synthesize macromolecules, such as nucleic acids and proteins, resulting in cell death. However, mutations leading to alterations in cytoplasmic membrane structure may lead to resistance.

Platensimycin (Table 28.4), produced by *Streptomyces platensis*, is an unusual antibiotic that inhibits fatty acid and lipid biosynthesis. Platensimycin is effective against a broad range of gram-positive *Bacteria*, including nearly untreatable infections caused by methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci. Platensimycin has a unique mode of action, shows no host toxicity, and there is no known potential for development of resistance by pathogens. We discuss the discovery of platensimycin in Section 28.7.

Check Your Understanding

- Explain the concept of selective toxicity in terms of antimicrobial therapy.
- How does the activity of each antibiotic class lead to control of the affected pathogens?
- What are the sources of aminoglycosides, tetracyclines, macrolides, daptomycin, and platensimycin?

Figure 28.16 Reddish-orange urine from rifampin usage. The antibiotic rifampin is often administered to tuberculosis patients. However, a side effect of rifampin usage is that it turns urine and other body fluids reddish-orange.

28.6 Antimicrobial Drugs That Target Nonbacterial Pathogens

Many pathogens are nonbacterial—such as viruses or eukaryotes—and are often difficult to treat. Antiviral drugs often adversely affect the host as well as the pathogen because viruses depend on host cell biosynthetic machinery for their replication (Chapter 5). As a result, selective toxicity for viruses is achieved only with agents that preferentially affect unique viral replication pathways or the assembly of viral components. In spite of these limitations, a number of drugs are more toxic for viruses than for the host, and a few agents specifically target individual viruses. Fungi, protozoa, and helminths (worms) pose special problems for the development of effective drugs because these pathogens are eukaryotic, and therefore their cellular biology is similar to that of humans.

Antiviral Drugs

The most successful and commonly used agents for antiviral chemotherapy are the *nucleoside analogs*. These drugs are **nucleoside reverse transcriptase inhibitors (NRTIs)**, which work by inhibiting elongation of the viral nucleic acid chain by a nucleic acid polymerase. The first NRTI to be widely used was *zidovudine*, also called *azidothymidine (AZT)* (Table 28.5; ► Figure 31.49a), which effectively blocks reverse transcription and production of complementary DNA (cDNA) in HIV and other retroviruses (► Section 31.15). It is structurally similar to thymidine but is a dideoxy derivative, lacking the 3′-hydroxyl group. Another widely used nucleoside analog, *acyclovir* (Table 28.5), resembles guanosine and has been successfully used to control the symptoms of herpesvirus infections (► Section 31.14).

Some antiviral agents target the key enzyme of retroviruses, reverse transcriptase. *Nevirapine* (► Figure 31.49b), a **nonnucleoside reverse transcriptase inhibitor (NNRTI)**, binds directly to reverse transcriptase and inhibits reverse transcription (Table 28.5). Phosphonoformic acid, an analog of inorganic pyrophosphate, inhibits normal internucleotide linkages, preventing synthesis of viral nucleic acids. Because their action may affect normal host cell nucleic acid synthesis, both NRTIs and NNRTIs often induce some host toxicity.

Other anti-retroviral drugs include **protease inhibitors** and *enfuvirtide*, a **fusion inhibitor** (Table 28.5). Protease inhibitors disrupt viral replication by binding the active site of HIV protease (see Figure 28.20a), preventing this enzyme from processing large viral polyproteins into several individual viral components (◄ Section 11.8) including reverse transcriptase and integrase. Enfuvirtide (marketed as Fuzeon®) is a 36-amino-acid synthetic peptide that binds to the gp41 membrane protein of HIV; this stops the conformational changes necessary for the fusion of HIV with T lymphocyte membranes, thus preventing infection of host immune cells by HIV (► Figure 31.44).

A single category of drugs limits influenza infection: The *neuraminidase inhibitors* include oseltamivir (marketed as Tamiflu®), zanamivir (marketed as Relenza®), and peramivir (marketed as Rapivab®). These drugs block the active site of neuraminidase (◄ Figure 11.24) in influenza A and B viruses, inhibiting virus release from infected cells (Table 28.5). Oseltamivir is used for both treatment and prophylaxis of influenza, but its use has, in some cases, been

TABLE 28.5 Antiviral compounds

Examples	Mechanism of action	Virus affected
Enfuvirtide	Blocks fusion of HIV with T lymphocyte membrane	HIV (human immunodeficiency virus)
α-, β-, γ-Interferon	Induces proteins that inhibit viral replication	Broad spectrum (host-specific)
Oseltamivir and zanamivir	Block active site of influenza neuraminidase	Influenza A and B
Nevirapine	Reverse transcriptase inhibitor	HIV
Acyclovir (► Figure 31.43)	Viral polymerase inhibitor	Herpesviruses, <i>Varicella zoster</i>
Zidovudine (AZT) (► Figure 31.49a)	Reverse transcriptase inhibitor	HIV
Ribavirin	Blocks capping of viral RNA	Respiratory syncytial virus, influenza A and B, Lassa fever
Cidofovir	Viral polymerase inhibitor	Cytomegalovirus, herpesviruses
Tenofovir (TDF)	Reverse transcriptase inhibitor	HIV
Indinavir, saquinavir (Figure 28.20b)	Viral protease inhibitors	HIV

linked to adverse side effects that include behavioral abnormalities, especially in children. Zanamivir and peramivir are suitable for children, but because zanamivir is an inhaled drug, it is not recommended for those with asthma or other respiratory conditions.

Recall from Chapter 26 that virus-infected cells release small cytokine proteins called *interferons* that trigger a defensive response in neighboring host cells (◄ Section 26.10). If produced and administered properly, interferons may have potential use as prescribed antimicrobial agents. The clinical utility of interferons depends on whether they can be delivered to specific areas in the host to stimulate the production of antiviral proteins in uninfected host cells. Alternatively, appropriate interferon stimulators, such as viral nucleotides, nonvirulent viruses, or even synthetic nucleotides, if given to host cells prior to infection, may induce natural production of interferon.

Drugs That Target Eukaryotic Pathogens

Fungi cause a number of serious diseases (► Sections 34.1 and 34.2), and their treatment is complicated by the fact that many antifungal agents target metabolic pathways that are shared by fungi and their host cells, thus making the drugs toxic. As a result, many antifungal drugs can be used only for topical (surface) applications (Table 28.6).

A major group of antifungal compounds are *ergosterol inhibitors*, which work either by interacting directly with ergosterol or inhibiting its synthesis (Table 28.6). Ergosterol is present in fungal cytoplasmic membranes in place of the cholesterol found in animal cell cytoplasmic membranes. Important ergosterol inhibitors include

TABLE 28.6 Antifungal agents			
Category	Target	Examples	Use
Allylamines	Ergosterol synthesis	Terbinafine	Oral, topical
Aromatic antibiotic	Mitosis inhibitor	Griseofulvin	Oral
Azoles	Ergosterol synthesis	Clotrimazole	Topical
		Fluconazole	Oral
		Miconazole	Topical
Chitin synthesis inhibitor	Chitin synthesis	Nikkomycin Z	Experimental
Echinocandins	Cell wall synthesis	Caspofungin	Intravenous
Nucleic acid analogs	DNA synthesis	5-Fluorocytosine	Oral
Polyenes	Ergosterol synthesis	Amphotericin B	Oral, intravenous
		Nystatin	Oral, topical
Polyoxins	Chitin synthesis	Polyoxin A and B	Agricultural

the *polyene* antibiotics, which are produced by species of *Streptomyces* bacteria. Polyenes bind specifically to ergosterol, causing membrane permeability and cell death (Figure 28.17). By contrast, *azoles* and *allylamines* are broad-spectrum antifungal drugs that work by selectively inhibiting ergosterol biosynthesis. Treatment with these drugs causes membrane damage and alteration of critical membrane transport activities.

Echinocandins are cell wall inhibitors that block the activity of 1,3- β -D-glucan synthase, the enzyme that forms β -glucan polymers in the fungal cell wall (Figure 28.17 and Table 28.6). Because mammalian cells do not have 1,3- β -D-glucan synthase (or cell

walls), the activity of these agents selectively kills fungal cells. Echinocandins are often used to treat *Candida* yeast infections, as well as some fungal pathogens that are resistant to azoles and other agents.

Fungal cell walls also contain chitin, a polymer of *N*-acetylglucosamine found only in fungi and insects. Several *polyoxins* inhibit cell wall synthesis by interfering with chitin biosynthesis (Figure 28.17). Although not used clinically, polyoxins are widely used as agricultural fungicides. Other antifungal drugs inhibit folate biosynthesis, interfere with DNA topology during replication, or, in the case of drugs such as griseofulvin, disrupt microtubule aggregation during mitosis (Figure 28.17). Moreover, the nucleic acid analog 5-fluorocytosine (flucytosine) is an effective nucleic acid synthesis inhibitor in fungi.

Historically, protozoan-caused diseases, especially malaria, have been treated with *quinine* or, more recently, quinine derivatives, such as chloroquine and mefloquine. However, extensive resistance to these drugs among the *Plasmodium* spp. that cause malaria (► Section 34.5) has led to the development of artemisinin-based alternatives. Artemisinin is produced in low amounts by the Chinese wormwood plant (*Artemisia*), which has traditionally been used to control the cyclic fever associated with malaria. A more recent discovery has shown artemisinin to also be an effective treatment for certain helminth diseases, such as schistosomiasis (► Section 34.7). Using the techniques of synthetic biology, a genetically engineered yeast strain is now being used to produce artemisinin, making the drug more widely available (◀ Section 12.11 and Figure 12.37).

The drug of choice to combat many parasitic protozoans is *metronidazole* (or the related drug *tinidazole*), which targets anaerobic pathogens and is therefore also useful against infections caused by clostridia. Infections with *Giardia intestinalis* (giardiasis), *Trichomonas vaginalis* (trichomoniasis), and especially *Entamoeba histolytica* (amebic dysentery) have all been treated successfully with these drugs (► Sections 34.3 and 34.4). The related protist *Cryptosporidium parvum* (cryptosporidiosis) is often treated with *nitazoxanide*, a drug that has also been effective against helminths. However, perhaps the most widely used antihelminthic drugs are *praziquantel*, for treating

Figure 28.17 Targets of some antifungal agents. Traditional antibacterial agents are generally ineffective because fungi are eukaryotic cells. The cell wall and ergosterol (present in the cytoplasmic membrane) of fungal cells make good selective targets because they are unique structures not present in vertebrate host cells.

schistosomiasis and tapeworm infections, and *mebendazole* (and similar drugs), for treating a variety of helminth infections, including tapeworms, pinworms, hookworms, trichinosis, and ascariasis (► Section 34.7).

We now tackle the topic of drug resistance, a consequence of the widespread use of antimicrobial agents in clinical and veterinary medicine and animal husbandry.

Check Your Understanding

- What steps in the viral maturation process are inhibited by nucleoside analogs? By protease inhibitors? By interferons?
- Why are there fewer clinically effective antifungal and anti-parasitic agents than antibacterial agents?

28.7 Antimicrobial Drug Resistance and New Treatment Strategies

Antimicrobial drug resistance is the acquired ability of a microorganism to resist the effects of an antimicrobial agent to which it was formerly susceptible. As we have discussed, many microorganisms produce antibiotics, and genes encoding antibiotic resistance are present in virtually all of them. Horizontal gene transfer (Chapters 9 and 13) between and among microorganisms disseminates antimicrobial drug resistance.

Antimicrobial Drug Resistance

Common mechanisms of bacterial resistance to antibiotics were discussed in the context of microbial growth in Section 8.11 and depicted in Figure 8.28, and some examples are listed in Table 28.7.

Antibiotic resistance can be genetically encoded on the bacterial chromosome, but more often, antibiotic-resistant bacteria isolated from patients contain drug-resistance genes located on horizontally transmitted *R (resistance) plasmids* (◀ Section 6.2). Enzymes encoded by genes on *R* plasmids confer resistance by any of three classes of mechanisms: modifying and inactivating the drug, preventing uptake of the drug, or actively pumping the antibiotic out of the cell, a process called *efflux* (Table 28.7).

The widespread use of antibiotics (Figure 28.13a) provides favorable conditions for the spread of *R* plasmids because they carry genes that confer an immediate selective advantage. The ubiquity of resistance genes limits the long-term use of any single antibiotic as an effective antimicrobial agent. A classic example is the development of multidrug resistance in the bacterium *Neisseria gonorrhoeae*. Penicillin, widely used to treat gonorrhea into the 1980s, became ineffective and was replaced by ciprofloxacin, which, in turn, lost much of its efficacy after just 10 years of use (Figure 28.18). This prompted a switch in treatment to the β -lactamase-resistant ceftriaxone, and more recently, a combination of ceftriaxone and azithromycin. Such combinations of two unrelated antimicrobial agents often reduce resistance because it is less likely that a mutant strain resistant to one antibiotic will also be resistant to the second antibiotic. However, certain *R* plasmids confer multiple drug resistance and can thwart multiple antibiotic therapy as a clinical strategy.

Overuse of antibiotics also accelerates resistance. In addition to their traditional use as a treatment for infections, antibiotics are widely used as supplements to farm animal feeds both as growth-promoting substances and as prophylactic additives to prevent the occurrence of disease. For example, broad-spectrum antibiotics

TABLE 28.7 Bacterial resistance to antibiotics

Resistance mechanism	Antibiotic example	Genetic basis of resistance	Mechanism present in
Reduced permeability	Penicillins	Chromosomal	Gram-negative bacteria
Inactivation of antibiotic Examples: β lactamases; modifying enzymes, such as methylases, acetylases, phosphorylases, and others	Penicillins	Plasmid and chromosomal	<i>Staphylococcus aureus</i> Enteric bacteria
	Chloramphenicol	Plasmid and chromosomal	<i>Neisseria gonorrhoeae</i> <i>Staphylococcus aureus</i>
	Aminoglycosides	Plasmid	Enteric bacteria
Alteration of target Examples: RNA polymerase, rifamycin; ribosome, erythromycin and streptomycin; DNA gyrase, quinolones	Erythromycin	Chromosomal	<i>Staphylococcus aureus</i>
	Rifamycin		Enteric bacteria
	Streptomycin		Enteric bacteria
	Norfloxacin		Enteric bacteria <i>Staphylococcus aureus</i>
Development of resistant biochemical pathway	Sulfonamides	Chromosomal	Enteric bacteria <i>Staphylococcus aureus</i>
Efflux (pumping out of cell)	Tetracyclines	Plasmid	Enteric bacteria
	Chloramphenicol	Chromosomal	<i>Staphylococcus aureus</i> <i>Bacillus subtilis</i>
	Erythromycin	Chromosomal	<i>Staphylococcus aureus</i>

Figure 28.18 The emergence of multidrug resistance in *Neisseria gonorrhoeae*.

Resistance to penicillin developed in the 1980s to the point that it could no longer be recommended for treatment of gonorrhea, at which point ciprofloxacin, a quinolone, became the drug of choice. By the early 2000s, resistance to ciprofloxacin prompted a change to ceftriaxone. The current gonorrhea treatment recommendation is a combination of ceftriaxone plus azithromycin.

widely used clinically, such as the fluoroquinolone ciprofloxacin, were used extensively as a feed additive, especially by the poultry industry. In addition, although the trend is improving, antibiotics are used in clinical practice far more often than necessary, and this problem is compounded by patient noncompliance—many patients stop taking antibiotics as soon as they feel better. Antibiotic resistance can be minimized if drugs are used only for treatment of susceptible pathogens and are given in sufficiently high doses and for sufficient lengths of time to eradicate the pathogen before resistant mutants can propagate.

To prevent the further emergence of multidrug-resistant pathogens, the U.S. Centers for Disease Control and Prevention (CDC) publishes guidelines stressing the importance of vaccination, rapidly and accurately diagnosing and treating infections, using antimicrobial agents prudently, and preventing pathogen transmission.

New Drugs and New Treatment Strategies

Conservative, appropriate administration of antibiotics can prolong or even resurrect the clinical usefulness of available drugs, but the long-term solution to antimicrobial drug resistance requires continuous development of new drugs through design or discovery. Developing new analogs of existing antimicrobial compounds is usually more cost effective than discovering new drugs, and analogs may actually have greater antimicrobial activity than the parent compound. For example, using natural penicillin as the starting compound, systematic chemical substitution of the *N*-acyl group can generate hundreds of penicillin derivatives, many with broad-spectrum activity (Figure 28.14). Using this basic strategy,

semisynthetic analogs of β -lactam antibiotics, tetracycline, and vancomycin (Figure 28.19) have been synthesized.

Novel antimicrobial compounds are more difficult to identify than analogs of existing drugs because new antimicrobial compounds must work at unique sites in metabolism or be structurally dissimilar to existing compounds to avoid resistance mechanisms. Computer-based methods accelerate novel compound design by maximizing molecular binding in a virtual environment. A dramatic success in computer-directed drug design was the development of *saquinavir*, a protease inhibitor that impedes the multiplication of HIV in infected individuals by binding the active site of the HIV protease enzyme (Figure 28.20). As an analog of the HIV precursor protein, saquinavir (marketed as Invirase®) displaces the authentic protease substrate and inhibits virus maturation. Several other computer-designed protease inhibitors, including *indinavir* (marketed as Crixivan®) (Figure 28.20b), are currently in use for the treatment of HIV/AIDS (► Section 31.15).

Another strategy to overcome antimicrobial resistance is to select for antibiotics that interact with unexploited targets. Platensimycin is the first antimicrobial drug targeted to disrupt bacterial lipid biosynthesis (Table 28.4 and Figure 28.12). Platensimycin is especially active against gram-positive pathogens, including drug-resistant staphylococci and enterococci. To select an agent for a defined target, in this case an enzyme in the bacterial lipid synthesis pathway, scientists used antisense RNA (◄ Section 7.12) to limit the amount of accessible mRNA required to produce a key lipid biosynthesis enzyme in *Staphylococcus aureus*. This reduced fatty acid synthesis in the cells

Figure 28.19 Vancomycin. Many pathogenic strains now show intermediate drug resistance to the parent structure of vancomycin, but chemically substituting the carbonyl oxygen at the position shown in red with a methylene ($=\text{CH}_2$) group restores much of the lost activity. Like penicillin, vancomycin prevents cross-linking of peptidoglycan and is most effective against gram-positive pathogens.

(a) HIV protease

Saquinavir

Indinavir

(b)

Figure 28.20 Computer-generated anti-HIV drugs. (a) The HIV protease homodimer. Individual polypeptide chains are shown in green and blue. A peptide (yellow) is bound in the active site. HIV protease cleaves an HIV precursor protein, a necessary step in virus maturation. Blocking of the protease site by the bound peptide inhibits precursor processing and HIV maturation. This structure is derived from coordinates in the Protein Data Bank. (b) These anti-HIV drugs are peptide analogs called protease inhibitors that were designed by computer to block the active site of HIV protease. The areas highlighted in orange show the regions analogous to peptide bonds in proteins.

and increased the sensitivity of the crippled *S. aureus* strain to antibiotics that inhibit fatty acid synthesis. After screening thousands of natural products from potential antibiotic producers, scientists isolated platensimycin from the soil bacterium *Streptomyces platensis*, a species of the filamentous *Actinobacteria* (◀ Section 16.12). This strategy identifies target-specific antibiotics present in low concentrations and is applicable to virtually any target for which the gene sequence (and, hence, the corresponding antisense RNA sequence) is known.

The efficacy of some antibiotics can be preserved if they are administered with compounds that thwart antibiotic resistance mechanisms. For example, several β -lactam antibiotics can be combined with β -lactamase inhibitors to preserve antibiotic activity in β -lactam-resistant microbes. For instance, amoxicillin (similar to ampicillin, Figure 28.14) can be mixed with the β -lactamase inhibitor clavulanic acid to produce the combination drug Augmentin®. The inhibitor binds β -lactamase (produced by the resistant pathogen) irreversibly. This prevents amoxicillin from being degraded and maintains the efficacy of the antibiotic.

Drug combination therapy has also revolutionized treatment of HIV infections. Currently, a combination therapy consisting of nucleoside analogs and a protease inhibitor is recommended. This drug treatment protocol is termed HAART, for *highly active anti-retroviral therapy* (▶ Section 31.15). As with antibacterial combination regimens, HAART is designed to target two independent viral functions: nucleoside analogs target virus replication, and protease inhibitors target virus maturation. Because the probability of a virus developing resistance to multiple drugs is much less than the probability of it becoming resistant to a single drug, HAART therapy has been a successful strategy in controlling HIV infections.

Check Your Understanding

- Identify the basic mechanisms of antibiotic resistance in bacteria and describe what practices encourage their dissemination.
- What does vancomycin have in common with penicillin? How can native vancomycin be improved?
- Explain the advantages and disadvantages of developing new drugs based on existing drug analogs. What other methods exist for developing new drugs?

CHAPTER REVIEW

I • Disorders and Deficiencies of the Immune System

28.1 Hypersensitivity is the induction by foreign antigens of antibody-mediated or cell-mediated immune responses that damage host tissue. In autoimmunity, the immune

response is directed against self antigens. Damage to host tissue is caused by the inflammation produced by immune mechanisms.

Q How do immediate and delayed-type hypersensitivities differ from one another in terms of immune effectors, target tissues, antigens, and clinical outcome?

- 28.2** Superantigens are components of certain bacterial and viral pathogens that bind outside the antigen-specific binding site of TCRs and, therefore, activate large numbers of T cells. Superantigen-activated T cells may produce diseases characterized by systemic inflammatory reactions. Immunodeficiency is the inability to generate a proper immune response, resulting in recurrent, uncontrollable infections by opportunistic pathogens. Some of the most severe immunodeficiency syndromes are SCID, caused by a genetic disorder, and AIDS, caused by HIV infection.

Q How do superantigens differ from conventional antigens in terms of initial T cell activation and clinical outcome? How does immunodeficiency resulting from SCID differ from that caused by HIV infection and AIDS?

II • Vaccines and Immunotherapy

- 28.3** Immunization induces artificial active immunity and is widely used to prevent infectious diseases. Vaccines are either attenuated or inactivated pathogens or pathogen products or are genetically engineered antigens. The latter eliminate exposure to pathogens and, in some cases, even to protein antigen. Application of this strategy is providing safer vaccines targeted to individual pathogen antigens.

Q List the immunizations recommended for children in the United States. For which of these have you been immunized? List the diseases for which you may have acquired immunity naturally.

- 28.4** A growing number of diseases, including a variety of cancers and autoimmune disorders, are being treated by immunotherapy, a clinical strategy that optimizes the adaptive immune response to a disease using bioengineered immune components. The identification of tumor-specific neoantigens in cancer cells can allow for production of customized monoclonal antibodies (mAbs), chimeric antigen receptor (CAR) T cells, and anticancer vaccines. The efficacy of immunotherapeutic treatments varies between individuals, and this may be linked to the composition of their gut microbiota.

Q What is a “neoantigen”? How are they identified, and how can they be used to develop mAbs, CAR T cells, and anticancer vaccines?

III • Drug Treatments for Infectious Diseases

- 28.5** Antibiotics are chemically diverse antimicrobial compounds produced by microorganisms. Each antibiotic works by inhibiting a specific cellular process in the target microorganisms. The β -lactam antibiotics, including penicillins and cephalosporins, target bacterial cell wall synthesis and are the most important class of clinical antibiotics. The aminoglycosides, macrolides, and tetracycline antibiotics selectively interfere with protein synthesis in *Bacteria*. The quinolones are an important class of synthetic antibacterial drugs that inhibit DNA synthesis. Daptomycin and platensimycin are structurally novel antibiotics that target cytoplasmic membrane functions and lipid biosynthesis, respectively.

Q What are the common sources for natural antibiotics? How do these antimicrobial drugs differ from growth factor analogs, such as the sulfa drugs? Why are β -lactam antibiotics generally more effective against gram-positive bacteria than against gram-negative bacteria?

- 28.6** Antiviral agents selectively target virus-specific enzymes and processes. Useful agents include analogs and compounds that inhibit nucleic acid polymerases and viral genome replication. Protease inhibitors interfere with viral maturation steps. Because fungi are *Eukarya*, antifungal agents exhibiting selective toxicity are difficult to find. Nevertheless, some effective antifungal agents are available, and they primarily target fungi-specific structures and biosynthetic processes.

Q Why is host toxicity a common problem with antiviral and antifungal drugs? Identify the targets that allow for selective toxicity of antifungal agents.

- 28.7** The use of antimicrobial drugs inevitably leads to resistance in the targeted microorganisms. The development of resistance can be accelerated by the indiscriminate use of antimicrobial drugs, and many pathogens have developed resistance. New antimicrobial compounds must continually be discovered and developed to deal with drug-resistant pathogens and to enhance our ability to treat infectious diseases. Computer-based modeling and other novel strategies are helping to address this challenge.

Q What practices contribute to the spread of antibiotic resistance? Explain how antisense RNA strategies can extend traditional methods of natural product selection for antibiotic discovery.

APPLICATION QUESTIONS

1. What problems would arise if a person had a hereditary deficiency that resulted in an inability to present antigens to Tc cells? What would the problems be if the person had a deficiency in presenting antigen to Th1 cells? To Th2 cells? To all T cells? What molecules might be deficient in each situation? Could a person having any one of these deficiencies survive in a normal environment? Explain for each.
2. Viruses and fungi present special problems for drug therapy. Explain the issues inherent in drug treatment of both groups

and explain whether you agree with the preceding statement. Give specific examples and suggest at least one group of agents that might target both types of infectious agents.

3. Describe three important reasons why semisynthetic penicillins were first developed. Which clinical challenges do each of these reasons address? What key part of the penicillin molecule must be retained for any semisynthetic penicillin to be active?

CHAPTER GLOSSARY

Allergen an antigen that elicits an immediate hypersensitivity (allergic) reaction upon exposure

Aminoglycoside an antibiotic, such as streptomycin, containing amino sugars linked by glycosidic bonds

Antibiotic a chemical substance produced by a microorganism that kills or inhibits the growth of another microorganism

Antimicrobial drug resistance the acquired ability of a microorganism to resist the effects of an antimicrobial agent to which it was formerly susceptible

Autoantibody an antibody that reacts to self antigens

Autoimmunity a harmful immune reaction directed against self antigens

β -lactam antibiotic penicillin, cephalosporin, or a related antibiotic that contains the four-membered heterocyclic β -lactam ring

Delayed-type hypersensitivity (DTH) an inflammatory allergic response mediated by Th1 lymphocytes

Fusion inhibitor a synthetic polypeptide that binds to viral glycoproteins, inhibiting fusion of viral and host cell membranes

Growth factor analog a chemical agent that has a similar structure to and blocks the uptake or utilization of a growth factor

Hypersensitivity an immune response leading to damage to host tissues

Immediate hypersensitivity an allergic response mediated by vasoactive products released from IgE-sensitized mast cells

Immunotherapy the treatment of a disease, especially cancer, using targeted therapeutic agents that either enhance or suppress the immune response

Macrolide erythromycin or a related antibiotic that contains a lactone ring bonded to sugars

Nonnucleoside reverse transcriptase inhibitor (NNRTI) a nonnucleoside compound that inhibits the action of retroviral reverse transcriptase by binding directly to the catalytic site

Nucleoside reverse transcriptase inhibitor (NRTI) a nucleoside analog compound that inhibits the action of retroviral reverse transcriptase by competing with nucleosides

Protease inhibitor a compound that inhibits the action of viral protease by binding

directly to the catalytic site, preventing viral protein processing

Quinolone a synthetic antibacterial compound that inhibits DNA gyrase and prevents supercoiling of bacterial DNA

Selective toxicity the ability of a compound to inhibit or kill a pathogen without adversely affecting the host

Sulfa drugs synthetic growth factor analogs that inhibit folic acid biosynthesis in *Bacteria*

Superantigen a pathogen product capable of eliciting an inappropriately strong inflammatory immune response by stimulating greater than normal numbers of T cells

Tetracycline an antibiotic characterized by the four-member naphthacene ring structure

Vaccination (immunization) the inoculation of a host with inactive or weakened pathogens or pathogen products to stimulate protective active immunity

Vaccine an inactivated or attenuated pathogen, or a harmless pathogen product, used to induce artificial active immunity

Shedding New Light on Diagnosing Tuberculosis

Few pathogens have caused more human deaths than *Mycobacterium tuberculosis* (photo), the causative agent of tuberculosis (TB). Due to the slow growth of *M. tuberculosis* and the sluggish progression of symptoms associated with TB, it can be difficult to rapidly and reliably detect active disease using traditional diagnostic tools. Further complicating the matter is that the prevalence of TB is high in less developed countries where adequate medical facilities or diagnostic supplies are often lacking. These factors can cause delayed diagnosis of TB, which compromises both patient care and public health efforts to control the disease.

For these reasons, a quick and reliable point-of-care diagnostic test for TB is sorely needed, and one may soon be on the way. Trehalose, a sugar that has been increasingly used as a food additive in recent years, is a precursor building block for the structurally unusual cell wall of *M. tuberculosis*. With this in mind, researchers have recently targeted trehalose as a chemical marker to reveal the presence of

M. tuberculosis in clinical specimens, such as in the sputum samples of patients suspected of having TB.

To use trehalose incorporation as a diagnostic assay, the sugar molecule had to be chemically modified to make it easily detectable. The indicator dye 4-*N,N*-dimethylamino-1, 8-naphthalimide (DMN) was chosen for this purpose because it fluoresces brightly in a hydrophobic environment. By conjugating DMN to trehalose (creating DMN-Tre) and subsequently allowing living *M. tuberculosis* cells to incorporate the metabolized DMN-Tre into their waxy (and thus hydrophobic) cell wall, the researchers were, within minutes, able to easily and specifically visualize cells of the glowing pathogen in sputum samples. In addition, because only healthy, growing cells incorporate DMN-Tre and fluoresce, this method may also provide a quick way to determine antibiotic susceptibility for individualized treatment plans.

I • Microbiology and the Healthcare Environment

Considering the prevalence of multidrug-resistant pathogens and healthcare-associated infections, the importance of safety protocols and personal protective equipment in the clinical microbiology laboratory cannot be overstated.

Clinical microbiology is a subdiscipline of microbiology whose focus is diagnosing infectious diseases by identifying pathogenic microbes and advising medical providers on treatment. Clinical laboratories must identify pathogens safely, efficiently, and reliably. The clinical microbiologist examines patient samples using direct observation, culture, immunological assays, and molecular tools to identify particular pathogens and rule out infection by others. Rapid and accurate identification of pathogens is critical for developing successful treatment strategies and maintaining disease control.

29.1 The Clinical Microbiology Laboratory

Clinical laboratories handle dangerous materials, and thus laboratory workers must adhere to strict safety protocols to prevent the spread of infectious agents. Standard laboratory practices for handling clinical samples have been established to minimize the risk of accidental laboratory infections. One only has to be reminded of

TABLE 29.1 Microbiology laboratory safety standards	
Rule	Implementation
Restrict access	Only laboratory workers and trained support personnel have access.
Practice good personal hygiene	Eating, drinking, applying cosmetics, and manipulating contact lenses are forbidden in the laboratory. Hand washing prevents spread of pathogens.
Use personal protective equipment (PPE)	Lab coats, gloves, eye protection, and respirators are recommended or required depending on the pathogens being handled. Face masks are part of PPE if respirators are not required.
Vaccinate	Personnel must be vaccinated against agents to which they may be exposed.
Handle specimens safely	Assume all clinical specimens are infectious and handle appropriately.
Decontaminate	After use or exposure, decontaminate specimens, surfaces, and materials by disinfecting, autoclaving, or incinerating. Wash health-care clothing (scrubs) frequently.

the 2014 Ebola hemorrhagic fever outbreak in West Africa (► Section 31.12) to appreciate how treating infected persons without paying rigorous attention to every safety detail can endanger the lives of medical personnel.

Laboratory Safety

The clinical laboratory has potential biohazards for all personnel and is especially dangerous for untrained personnel or those who do not employ the necessary precautions. All laboratories that handle human or primate tissue must have an occupational exposure control plan for handling bloodborne pathogens. This plan is specifically designed to protect workers from infection by hepatitis B virus (HBV, the cause of infectious hepatitis, ► Section 31.11) and human immunodeficiency virus (HIV, the cause of acquired immunodeficiency syndrome [AIDS], ► Section 31.15). The occupational exposure plan limits infection by all pathogens and typically includes the use of appropriate *personal protective equipment* (PPE), which includes a lab coat, gloves, eye protection, and face mask (Figure 29.1).

Proper training and enforcement of established safety procedures can prevent most accidental infections, which usually do not result from identifiable exposures like culture spills but instead from routine handling of patient specimens. Infectious aerosols generated during microbiological procedures are the most common causes of laboratory infections. Clinical laboratories follow the safety rules outlined in Table 29.1 to minimize laboratory infections. These general standards apply to all laboratories that handle potentially infectious agents and are the basis for all aspects of healthcare infection control. However, as discussed next, laboratories that handle particularly dangerous or transmissible agents adhere to additional rules and procedures to ensure a safe work environment.

Figure 29.1 Standard apparel for clinical laboratory safety. This technician is wearing proper personal protective equipment (PPE) for a clinical laboratory, including gloves, eye protection, lab coat, and face mask.

Microbiology
Art Activity:
Table 29.1
Microbiology
laboratory
safety standards

Figure 29.2 Conducting research in a BSL-4 (biosafety level 4) laboratory. BSL-4 is the highest level of biological control, affording maximum worker protection and pathogen containment. The researcher has a whole-body sealed suit with an outside air supply and ventilation system. Air locks control all access to the laboratory. All material leaving the laboratory is autoclaved or chemically decontaminated.

Biological Containment and Biosafety Levels

The level of containment used to prevent accidental infections or accidental environmental contamination (escape) in clinical, research, and teaching laboratories must be proportional to the biohazard potential of the organisms handled in the laboratory. Laboratories are classified according to their containment capabilities from least to greatest by their *biosafety level* (BSL), designated as BSL-1, BSL-2, BSL-3, or BSL-4 (Figure 29.2). Personnel in laboratories working at all biosafety levels must follow standard laboratory practices that ensure basic cleanliness and limit contamination (Table 29.1). The precautions, equipment, and operational costs increase with each biosafety level, but the rationale in each case is the same: Keep any potentially infectious agents confined to the laboratory.

Most colleges and universities have BSL-1 and BSL-2 laboratories for teaching and research. Standard clinical laboratories operate at BSL-2. The specialized physical requirements for BSL-3 facilities limit them to major clinical centers and research settings. Because BSL-4 facilities must ensure total isolation and physical containment of pathogens, only about fifty BSL-4 laboratories are operational worldwide. Most BSL-4 laboratories are associated with government facilities, such as the Centers for Disease Control and Prevention (CDC; Atlanta, Georgia, USA) and the U.S. Army Medical Research Institute of Infectious Diseases (USAMRIID; Fort Detrick, Maryland, USA).

Check Your Understanding

- The use of personal protective equipment (PPE) is required for clinical laboratory technicians. What protective apparel does PPE include?
- Identify and discuss the standard safety procedures adopted by microbiology laboratories. Under what biosafety level do most clinical laboratories operate? With what type of facility are most BSL-4 laboratories associated?

29.2 Healthcare-Associated Infections

The universal safety measures described in the previous section are implemented to contain infectious agents and prevent their transmission in laboratory settings. But despite the routine use of gloves and clean clinical clothing (“hospital scrubs”) in healthcare facilities, the accidental transfer of pathogens to patients in these environments is a common occurrence.

Mechanisms of Transfer of Healthcare-Associated Infections

A **healthcare-associated infection (HAI)**, also called a *nosocomial infection* (from the Latin *nosocomium*, meaning hospital), is an infection acquired by a patient during a stay at a healthcare facility (clinic, hospital, rehabilitation facility, etc.). HAIs cause significant morbidity (incidence of *disease* in a population) and mortality (incidence of *death* in a population). An estimated 10% of patients admitted to healthcare facilities in the United States acquire HAIs, and up to 2 million HAIs occur annually, leading directly or indirectly to about 75,000 deaths. Some of the common risk factors for acquiring infectious diseases in healthcare settings are summarized in Table 29.2.

TABLE 29.2 Risk factors for hospital-acquired infections (HAIs)	
Risk factor for HAI	Rationale
Patients	Patients are already ill or immunocompromised
Newborn infants and the elderly	Not fully immune competent
Infectious disease patients	Pathogen reservoirs
Patient proximity	Increases cross-infection
Healthcare personnel	Can transfer pathogens between and among patients; healthcare personnel may be asymptomatic disease carriers
Medical procedures (blood draws, etc.)	Breaching the skin barrier can introduce pathogens
Surgery	Exposes internal organs, may introduce pathogens, and causes stress, which lowers resistance to infection
Anti-inflammatory drug treatment	Lower resistance to infection
Antibiotic treatment	May select for resistant and opportunistic pathogens

Some HAIs are acquired from patients with communicable diseases, but others are caused by pathogens that are selected for and maintained within the hospital environment, spread by cross-infection from patient to patient or from healthcare personnel. Healthcare-associated pathogens are often present as normal microbiota in either patients or healthcare staff. Therefore, healthcare facilities are high-risk environments for the spread of infections because these facilities concentrate individuals who have infectious disease or are at risk for acquiring infectious disease because of underlying health conditions. Such conditions often lead to a compromised immune system and increased susceptibility to pathogens. The frequency of HAIs at different sites of the body is shown in **Figure 29.3**.

Common Causative Agents of HAIs

Most HAIs are caused by a relatively short list of pathogens (**Table 29.3**), but many other infectious agents can cause HAIs. *Staphylococcus aureus* is one of the most important and widespread HAI pathogens (► Section 31.9). It is the most common cause of pneumonia, the third most common cause of blood infections, and is particularly problematic in nurseries. Many hospital strains of *S. aureus* are unusually virulent and are resistant to common antibiotics, making treatment especially difficult (see Explore the Microbial World, “MRSA—A Formidable Clinical Challenge”). The staphylococci are the most common cause of bloodborne HAIs and are also prevalent in pus-forming wound infections.

Staphylococcus and *Enterococcus*, as well as *Escherichia coli*, *Klebsiella pneumoniae*, and various other *Enterobacteriaceae*, all have the potential to cause HAIs, but they are also members of the normal microbiota of most individuals, making it essentially impossible to eliminate these potential pathogens from healthcare settings. In addition, these organisms can acquire multidrug resistance by

horizontal gene flow (Chapter 9). Pathogens that are not part of the normal microbiota, such as species of *Acinetobacter* and *Mycobacterium*, can be eliminated from the healthcare environment. These pathogens are carried into the healthcare facilities by infected individuals or, in the case of some mycobacteria, as airborne contaminants.

Prevention of HAIs requires cooperation between the healthcare facility infection-control team and the rest of the facility staff, including direct healthcare workers and supporting staff, such as housekeeping. Infection control starts with management of incoming patients at the point of entry to the healthcare facility; incoming patients should be assessed for possible infections and isolated as necessary to prevent spread of infections to staff and other patients. In addition, periodic testing of healthcare personnel for key pathogens, such as methicillin-resistant *Staphylococcus aureus* (MRSA), can identify healthy carriers. From this point, the healthcare facility staff employs standard procedures that limit infection, applying the same general precautions outlined for laboratory technicians in Table 29.1.

- How can the spread of HAIs be controlled?

II • Isolating and Characterizing Infectious Microorganisms

Although the emphasis on molecular diagnostic tools is growing in clinical laboratories, traditional specimen collection and pathogen cultivation techniques are universally used and provide accurate disease diagnosis in a timely manner.

The growth and observation of pathogens from patient specimens are important strategies for identification of the causative agent of an infectious disease. Identification leads to antimicrobial drug susceptibility testing and development of a specific treatment plan. We begin by looking at methods for collecting, culturing, and identifying pathogens, followed by methods used to determine drug susceptibility.

29.3 Workflow in the Clinical Laboratory

Collecting specimens from infectious patients and subsequently culturing pathogens using a variety of growth media is a necessary and routine practice in clinical medicine. Combined with microscopic observation, these methods allow for direct detection and identification of causative agents of disease.

Collecting Specimens and Detecting and Culturing Pathogens

Proper clinical diagnosis of infectious diseases requires that pathogens be identified from tissue or fluid samples using a variety of

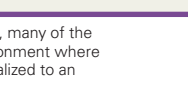

Figure 29.3 Frequency of healthcare-associated infections (HAIs) in different sites of the body. Up to 2 million HAIs occur annually in the United States. Data are from the Centers for Disease Control and Prevention.

TABLE 29.3 Common healthcare-associated pathogens

Pathogen	Common infection sites and diseases	Micrographs ^b	
^a <i>Acinetobacter</i>	Wound/surgical site, bloodstream, pneumonia, urinary tract		<i>Acinetobacter</i>
<i>Burkholderia cepacia</i>	Pneumonia		<i>B. cepacia</i>
<i>Clostridioides (Clostridium) difficile</i>	Gastrointestinal tract		<i>C. difficile</i>
^a <i>Enterobacteriaceae</i> , carbapenem-resistant, especially <i>Escherichia coli</i> , <i>Proteus mirabilis</i> , and <i>Klebsiella pneumoniae</i>	Urinary tract, pneumonia, wound/surgical site, bloodstream		<i>E. coli</i>
			<i>Klebsiella</i>
^a Vancomycin-resistant <i>Enterococcus</i>	Wound/surgical site, bloodstream, urinary tract		<i>Enterococcus</i>
Hepatitis	Chronic liver infection		Hepatitis B virus
Human immunodeficiency virus (HIV)	Immunodeficiency		HIV
Influenza virus	Pneumonia		Influenza virus
^a <i>Mycobacterium tuberculosis</i>	Chronic lung infection		<i>M. tuberculosis</i>
<i>Mycobacterium abscessus</i>	Skin and soft tissue infections		
Norovirus	Gastroenteritis		Norovirus
^a <i>Staphylococcus aureus</i> Methicillin-resistant (MRSA) and vancomycin-intermediate and resistant strains	Bloodstream, pneumonia, endocarditis		<i>S. aureus</i>

^aAntibiotic-resistant organisms that exhibit multiple drug resistance. Because of the ease by which multiple-drug-resistant plasmids can be transmitted, many of the pathogens listed as well as members of the normal microbiota could be or become drug resistant in the highly selective nature of the healthcare environment where antibiotics are used routinely and extensively. In addition to the pathogens listed, other extremely pathogenic agents (such as Ebola virus) could be localized to an isolation unit of a healthcare facility, thus making that part of the facility especially dangerous for disease transmission.

Humphrey.

Explore the Microbial World

MRSA—A Formidable Clinical Challenge

Staphylococcus aureus is an opportunistic human pathogen that colonizes an estimated one-third of the population. In such individuals, this gram-positive bacterium usually exists as an innocuous member of the normal microbiota of the skin and mucous membranes, especially in the nasal epithelium. Although most complications from staphylococci occur in the form of local skin infections, *S. aureus* may in

that precipitate blood plasma components and promote the formation of a protective matrix around the bacterial cells that inhibits the activity of phagocytes at sites of infection. In addition, protein A is a surface protein on *S. aureus* that obstructs opsonization by antibodies and complement (◀ Section 26.9), effectively camouflaging the pathogen and further impeding phagocytosis. *S. aureus* also

resistant to these drugs is increasing as global use of antibiotics remains extremely high (see Figure 28.13a). Infections caused by multidrug-resistant strains of *S. aureus* are often treated with *methicillin*, a powerful semisynthetic β -lactam drug that is among the last treatment options available in these cases. However, an alarming percentage of *S. aureus* strains have also developed resistance to methicillin in recent years. These methicillin-resistant *S. aureus* (MRSA) strains have been especially prevalent as healthcare-associated infections (Section 29.2).

Clinical diagnosis of MRSA infections depends upon either culture-based techniques, which often include the use of chromogenic agar media (Figure 1) or nucleic acid-based tests (Section 29.8). Confirmation of infection must be followed by antibiotic susceptibility testing (Section 29.4) to determine the best treatment strategy. Typically, treatments are case-specific and require a non- β -lactam antibiotic such as vancomycin, tetracycline, or sulfa drugs (◀ Section 28.5), often administered intravenously.

The global incidence of MRSA infection remains high; almost 80,000 cases are documented every year in the United States alone, and several regions of the world have reported increases in MRSA prevalence in recent years, especially in India. Interestingly, the prevalence of healthcare-associated MRSA infections has steadily declined in recent years while that of community-associated MRSA infections has increased. The United States Centers for Disease Control and Prevention estimates that MRSA carriers comprise 2% of the population. Considering its prevalence and extensive multidrug resistance, MRSA may continue to prove a difficult pathogen to control.

Figure 1 Methicillin-resistant *Staphylococcus aureus* (MRSA). Colonies of MRSA on this chromogenic agar medium (left) appear pink, whereas colonies of other bacteria appear blue. The colorized scanning electron micrograph on the right shows cells of MRSA (yellow) embedded in a matrix of cellular debris (orange).

some cases invade other tissues of the body, including the bloodstream, where a host of virulence factors it produces may transform this bacterium from a harmless commensal to a serious pathogen capable of causing life-threatening disease.

Virulence factors of *S. aureus* include coagulase and clumping factor, two proteins

produces several potent exotoxins, including α -hemolysin (lyses blood cells), enterotoxin B (causes food poisoning), and toxic shock syndrome toxin-1 (causes life-threatening toxic shock).

Many *S. aureus* infections are effectively treated using β -lactam antibiotics, such as various penicillins, but the number of strains

microbiological, immunological, and molecular biological techniques (Figure 29.4). Patient specimens must be collected aseptically from the site of the infection, and the sample size must be large enough to ensure an inoculum sufficient for growth. In addition, the requirements for organism survival, such as oxic versus anoxic conditions, must be maintained at all times, and the sample should be processed quickly to avoid degradation. Sterile swabs are often used to obtain samples from infected areas, including wounds, nares, or throat (Figure 29.5), and the swab is then used to inoculate a suitable growth medium.

Many pathogens can be detected by direct means using one or more of several diagnostic tests. For example, the microscopic observation of gram-negative diplococci, especially inside neutrophil inclusions, in a urethral exudate sample is diagnostic for infection with *Neisseria gonorrhoeae* (Figure 29.6a), the causative agent of the sexually transmitted disease gonorrhea (▶ Section 31.13). However, the reliability of any diagnostic test depends on both the *specificity* and the *sensitivity* of the test. **Specificity** is the ability of the test to recognize a single pathogen. High specificity reduces the

Figure 29.4 Laboratory identification of microbial pathogens. The flowchart shows alternative paths for identifying pathogens or pathogen exposure in the clinical laboratory.

likelihood of a *false-positive* result. **Sensitivity** defines the smallest quantity of a pathogen or a pathogen product that can be detected. High sensitivity minimizes the likelihood of a *false-negative* reaction. For the detection of *N. gonorrhoeae*, the specificity of Gram-stained smears of urogenital exudates is high for both men and women ($\geq 95\%$), so false-positive tests for gonorrhea are rare. By contrast, the sensitivity of Gram-stained smears of urogenital exudates for the detection of *N. gonorrhoeae* is about 80% greater for men than for women. Thus, in suspected cases of gonorrhea in females, *false-negative* Gram stains are relatively common. Females must therefore be examined by more sensitive methods, including culture techniques (Figure 29.6b), to establish or confirm a diagnosis of gonorrhea.

Specific pathogens can be selectively grown, isolated, and identified from patient specimens using specialized growth media and incubation conditions to establish an *enrichment culture* (Sections 19.1 and 19.2). For primary enrichment, clinical samples are inoculated on general-purpose media, such as *blood agar* (Figure 29.7a) and *chocolate agar* (so called because it contains heat-lysed blood, making it brown in color; Figure 29.7b), which support the growth

of a variety of microorganisms. To aid in the isolation and identification of specific pathogens, medical technologists use various *selective* and *differential* growth media. **Selective media** are specialized culture media that contain inhibitory agents for the purpose of allowing some organisms to grow but not others. **Differential media** allow identification of organisms based on the appearance of the culture after growth. For example, eosin–methylene blue (EMB) agar is a selective medium because the methylene blue it contains inhibits the growth of gram-positive bacteria. EMB agar is also a differential medium because it distinguishes gram-negative

Figure 29.5 Specimens from the upper respiratory tract. (a) Throat swab. (b) Nasopharyngeal swab passed through the nose. (c) Swabbing the inside of the nose.

Figure 29.6 Identification of *Neisseria gonorrhoeae*, the cause of gonorrhea. (a) Cells of gram-negative *N. gonorrhoeae* within human polymorphonuclear leukocytes (neutrophils) from a urethral exudate. (b) Colonies of *N. gonorrhoeae* growing on a filter placed on Thayer–Martin agar. Oxidase reagent, which turns colonies dark purple if they contain cytochrome *c*, has been added to the filter. The dark color of the colonies shows that *N. gonorrhoeae* is oxidase-positive.

Figure 29.7 Enriched media. (a) *Burkholderia* growing on sheep blood agar (SBA); the red color is from blood suspended in the trypticase soy agar medium. (b) *Francisella tularensis* growing on chocolate agar; the brown color is due to heat-lysed blood in the trypticase soy agar medium. (c) *Escherichia coli*, a lactose fermenter (left), and *Pseudomonas aeruginosa*, a non-lactose fermenter (right) growing on eosin-methylene blue (EMB) agar. The reflective, greenish-yellow sheen of the colonies on the left identifies *E. coli* as a lactose fermenter.

bacteria that can ferment lactose from those that cannot. Lactose fermenters, such as *Escherichia coli*, acidify the medium and produce dark colonies that may have a reflective metallic green sheen; non-lactose fermenters, such as *Pseudomonas aeruginosa*, produce opaque or translucent colonies (Figure 29.7c).

Blood and Cerebrospinal Fluid Specimens

Pathogens in liquid tissue samples, such as blood and cerebrospinal fluid (CSF), are routinely detected using automated culture systems. For a suspected case of meningitis, a CSF specimen is obtained by a procedure called a *lumbar puncture* (spinal tap) in which 3–5 ml of fluid is collected drop-by-drop from a needle inserted between lumbar vertebrae. CSF is sterile and clear in a healthy individual, and therefore fluid turbidity and high leukocyte counts are indicators of infection. Similar to other liquid specimens (blood, urine, sputum, wound exudates, etc.), CSF is routinely examined by Gram staining and used to inoculate selective culture media.

The standard procedure for obtaining a blood sample is to aseptically draw 10–20 ml of blood from a vein and inject it into two culture bottles containing general-purpose growth media and an anticoagulant. One bottle is incubated aerobically, while the other

is incubated anaerobically (Figure 29.8); both are kept at 35°C for several days. Automated culture systems (Figure 29.8b) detect growth by measuring turbidity or fluorescence and by periodically monitoring the consumption of O₂ or the production of CO₂. Most clinically significant bacteria are recovered within 2 days, but growth of some pathogens, including mycobacteria and certain fungi, may take 3 to 5 days or longer. Cultures that exhibit growth are Gram stained and then inoculated onto specialized media for isolation and identification.

The most common pathogens found in blood include species of *Staphylococcus* and *Enterococcus*, but many other bacteria may cause blood infections. Computer databases are used to unambiguously identify clinical isolates by matching their metabolic reactions in various differential media to the biochemical patterns of known pathogens. The biochemical tests incorporated into differential media evaluate the presence or absence of enzymes that catabolize a specific substrate or substrates. Although hundreds of different biochemical tests are known, just a few key tests may be sufficient to identify some pathogens.

Urinary Tract and Fecal Cultures

Urinary tract infections (UTIs) are common, especially in women. In most cases, microorganisms infect the urinary tract by ascending into the bladder from the urethra. UTIs, often introduced through the use of urinary catheters (Figure 29.9), are among the most common healthcare-associated infections. Direct microscopic examination of urine from a UTI patient usually shows the presence of abnormal numbers of bacteria in the urine. A Gram stain may be done directly on urine samples to identify the morphology of urinary tract pathogens, such as gram-negative rods (various enteric bacteria), gram-negative cocci (species of *Neisseria*), and gram-positive cocci (especially species of *Enterococcus*).

Figure 29.8 Growth-dependent diagnostic testing for blood infections. (a) Cultures to assay both aerobic (left vial) and anaerobic (right vial) bacterial growth are inoculated with an aseptically drawn patient blood sample. (b) After inoculation, both vials in part a are incubated in an automated system that measures growth, for example, by turbidity, production of CO₂, or fluorescence. Matthew Sattley

Figure 29.9 Urinary catheter preparation. A healthcare professional prepares a urinary catheter. Although the apparatus is pre-sterilized, insertion of the catheter moves microorganisms from the urethra to the bladder and may result in a urinary tract infection, a common HAI.

A significant UTI typically results in bacterial counts of 10^5 or more cells per milliliter of urine. The most common causative agents of UTIs are enteric bacteria, with *E. coli* accounting for about 90% of cases. Blood agar is often used for primary enrichment and isolation of urinary tract pathogens. Selective and differential enteric media, such as EMB or MacConkey agar, permit differentiation of gram-negative lactose fermenters from non-lactose fermenters (Figure 29.7c) and inhibit the growth of possible gram-positive contaminants, such as commensal staphylococci. Additional differential and/or selective media may be used to identify urinary tract (or other) pathogens via traditional culturing techniques (Figure 29.10a, b) or rapid and convenient commercial media kits (Figure 29.10c).

Proper collection of fecal samples is important for the isolation of intestinal pathogens. Fecal specimens become more acidic during storage, so delay between sampling and processing must be minimized, especially for the isolation of acid-sensitive pathogens, such as *Shigella* and *Salmonella*. The fecal sample is placed in a sterile, sealed container for transport to the laboratory. Feces containing blood or pus, as well as feces from patients with suspected food-borne or waterborne infections, are inoculated into suitable media for isolation of potential pathogens. For example, many laboratories use selective and differential media to identify *E. coli* O157:H7 and *Campylobacter* species, important intestinal pathogens typically acquired from contaminated food or water (► Sections 33.11 and 33.12). Intestinal eukaryotic pathogens, such as *Giardia intestinalis* (► Section 34.4), are identified by direct microscopic observation of parasite cysts in diluted feces or through antigen-detection assays (see Figure 29.19c) rather than by culturing.

Wounds and Abscesses

Infections associated with injuries such as animal bites, burns, or cuts are sampled to recover the relevant pathogen. The results must be interpreted carefully to differentiate between infection and

contamination. Wound infections and abscesses often harbor a variety of normal microbiota, and swab samples from such lesions are frequently misleading. For abscesses and other purulent lesions, pus is aspirated with a sterile syringe and needle following disinfection of the skin surface. Internal purulent lesions are sampled by biopsy or from tissues removed in surgery. Gram stains are prepared directly from these specimens and examined microscopically.

Pathogens commonly associated with wound infections are *Staphylococcus aureus*, enteric bacteria, *P. aeruginosa*, and anaerobes, such as species of *Bacteroides* and *Clostridium*. Because of the varied oxygen requirements of these bacteria, samples must be obtained, transported, and cultured under anoxic as well as oxic conditions. The major isolation media are blood agar, selective media for enteric bacteria, and enrichment media containing additional supplements and reducing agents for obligate anaerobes. Widely used tools for the detection of MRSA in skin infections are *chromogenic agar media*. These selective and differential media contain a chromogenic substrate that, when metabolized, causes MRSA to produce distinctly colored colonies (see Explore the Microbial World, “MRSA—A Formidable Clinical Challenge”).

Genital Specimens and Culture for Gonorrhea

Sexually transmitted infections (STIs) that cause a purulent urethral discharge, especially in males, are classified as either nongonococcal or gonococcal urethritis. Nongonococcal urethritis is usually caused by *Chlamydia trachomatis* (► Section 31.13), *Ureaplasma urealyticum*, or *Trichomonas vaginalis* (► Section 34.4). Gonococcal urethritis is caused by *Neisseria gonorrhoeae* (► Section 31.13).

Cells of *N. gonorrhoeae* are gram-negative diplococci, a morphology not normally found in microbiota of the urogenital tract. Therefore, a Gram stain of a urethral, vaginal, or cervical smear revealing such cells, often surviving inside neutrophils (Figure 29.6a), is diagnostic for gonorrhea. Chocolate agar, a nonselective enriched medium, is often used for specimens suspected to contain *N. gonorrhoeae*. A selective medium used for isolation of *N. gonorrhoeae* is modified Thayer–Martin (MTM) agar (Figure 29.6b). This medium incorporates the antibiotics vancomycin, nystatin, trimethoprim, and colistin to suppress the growth of normal microbiota. These antibiotics have no effect on *N. gonorrhoeae* or *Neisseria meningitidis*, a cause of bacterial meningitis (► Section 31.5).

Inoculated plates are incubated in a humid atmosphere containing 3–7% CO₂ for 24–48 hours and then tested for their oxidase reaction (Figure 29.6b). Oxidase-positive, gram-negative diplococci growing on MTM or chocolate agar are presumed to be gonococci if the inoculum was derived from the urogenital tract. Definitive identification of *N. gonorrhoeae* requires determination of carbohydrate utilization patterns and immunological or nucleic acid probe tests. Laboratory testing of urogenital samples for *N. gonorrhoeae* (and the often-associated *C. trachomatis*) is often done using DNA amplification via polymerase chain reaction (PCR) or other molecular methods.

Culture of Anaerobic Pathogens

The identification of obligately anaerobic bacteria from patient specimens requires special isolation and culture methods (◄ Section 4.16). In general, media for anaerobes do not differ greatly from those used for aerobes, except that they (1) are usually richer in

(a)

(b)

(c)

Figure 29.10 Growth-dependent diagnostic tests for clinical isolates. (a) Differential media to assess sugar fermentation. Acid production is indicated by a color change (from red to yellow) of the pH-indicating dye in the medium. The appearance of a bubble in the small, inverted inner tube indicates gas production from fermentation. (b) Diagnostic test for enteric bacteria using triple-sugar iron (TSI) agar. The medium contains glucose, lactose, and sucrose. Organisms able to ferment only glucose cause acid formation only in the bottom of the tube, whereas lactose- or sucrose-fermenting organisms cause acid formation throughout the slant. The breaking up of the agar in the bottom of the tube indicates gas formation. Blackening of the agar is due to the reaction of hydrogen sulfide (from either protein degradation or thiosulfate reduction) with ferrous iron in the medium. From left to right: Fermentation of glucose only (typical of *Shigella*); growth but no fermentation (typical of *Pseudomonas*); hydrogen sulfide formation (typical of *Salmonella*); fermentation of sugars with gas production (typical of *Escherichia coli*). (c) Miniaturized media kits allow rapid identification of clinical isolates by running many biochemical tests on specimen samples at the same time. Four separate strips, each with a different isolate, are shown.

organic constituents, (2) contain reducing agents (usually cysteine or thioglycolate) to remove O_2 , and (3) contain a redox indicator to show that conditions are anoxic. Collection, handling, and processing of specimens must exclude exposure to air because O_2 is toxic to obligate anaerobes. Samples collected by syringe aspiration or biopsy must be immediately transferred to a sealed tube containing O_2 -free gas, usually with a dilute salt solution containing a reducing agent and a redox indicator to monitor O_2 contamination. Specimens are then used to inoculate anoxic media in an automated culture system or in an anoxic “glove box” filled with O_2 -free gases, usually a mixture of N_2 and H_2 (◀ Figure 4.29).

Several habitats in the body, including portions of the oral cavity and the lower intestinal tract, are anoxic and support the growth of anaerobic normal microbiota. Other parts of the body may also become anoxic if injury or disease reduces the blood supply to certain tissues, a condition called *ischemia*. These anoxic sites can then be colonized by obligate anaerobes. Although potentially pathogenic anaerobic bacteria are part of the normal microbiota, their numbers are kept in check through competition with other members of the microbial community. Under certain conditions, however, normally benign anaerobes may become opportunistic pathogens. A key example is *Clostridioides (Clostridium) difficile* (Table 29.3); this usually harmless member of the normal microbiota of the lower intestinal tract commonly emerges as a healthcare-associated pathogen when extended antibiotic therapy destroys competing microbes (◀ Section 24.11 and ▶ Section 30.7).

Check Your Understanding

- What are the key requirements for proper collection of clinical specimens, and why is it important that diagnostic tests for these specimens are both highly specific and sensitive?
- Identify culture methods and conditions used for blood, wound, urine, fecal, and genital specimens. Of what importance are selective and differential growth media in pathogen detection, and what special conditions must be maintained for the isolation of anaerobic pathogens?

29.4 Choosing the Right Treatment

Pathogens isolated from clinical specimens are identified to confirm medical diagnoses and to guide antimicrobial therapy. Appropriate and effective treatment for many pathogens is based on current experience and practices. For some pathogens, however, decisions about appropriate antimicrobial therapy must be made on a case-by-case basis. Such pathogens include those for which antimicrobial drug resistance is common (for example, gram-negative enteric bacteria), those that cause life-threatening disease (for example, meningitis caused by *Neisseria meningitidis*), and those that require bactericidal rather than bacteriostatic drugs (◀ Section 4.19) to prevent disease progression and tissue damage. Bactericidal agents are indicated, for example, for bacterial endocarditis (infection of the inner tissues of the heart, such as the heart valves), where total and rapid killing of the pathogen is critical for patient survival.

Minimum Inhibitory Concentration

Antimicrobial susceptibility is measured by determining the smallest amount of agent needed to completely inhibit the growth of the

tested organism in vitro (in laboratory culture), a value called the **minimum inhibitory concentration (MIC)**. The traditional way to determine the MIC for a given agent against a given organism is to prepare a series of culture tubes inoculated with the same number of microorganisms. Each tube contains the growth medium with an increasing concentration of the antimicrobial agent. After incubation, the tubes are checked for visible growth (turbidity), and the MIC is the lowest concentration of the agent that completely inhibits the growth of the test organism (◀ Section 4.19 and Figures 4.40 and 4.41).

In modern practice, the MIC of a given antimicrobial agent is typically determined using microliter amounts of media and reagents. For example, a miniaturized version of the MIC test uses a microtiter method with twofold dilutions of several antibiotics in medium inoculated with a standard amount of the test organism (**Figure 29.11a**). In clinical microbiology laboratories, tests for routine MIC determinations are usually automated using instruments that also allow for species identification of pure cultures obtained from patient specimens (Figure 29.11b, c).

Measuring Antimicrobial Susceptibility

The standard assay for antimicrobial activity is the *disk diffusion test* (Figure 29.11d–g). A Petri plate containing an agar medium is inoculated by evenly spreading a suspension of a pure culture of the suspected pathogen on the agar surface. Known amounts of different antimicrobial agents infused into filter-paper disks are then placed on the surface of the agar. The agents then diffuse from the disks into the agar during incubation, establishing a gradient; the farther the chemicals diffuse away from each disk, the lower is the concentration of the agent. At some distance from each disk, the effective MIC is reached. Beyond this point the microorganism is able to grow, but closer to the disk, growth is absent. A *zone of inhibition* forms with a diameter proportional to the concentration, solubility, diffusion coefficient, and overall effectiveness of the antimicrobial agent in the disk.

In addition to the disk diffusion test, Figure 29.11g depicts antibiotic susceptibility using the *epsilometer test* (Etest®). This assay uses a plastic strip infused with a predefined concentration gradient of

Figure 29.11 Antibiotic susceptibility testing. (a) Antibiotic susceptibility of a pathogen as determined by the broth dilution method in a microtiter plate. The organism is *Pseudomonas aeruginosa*. Each row has a different antibiotic in a series of concentrations. The highest concentration of antibiotic is in the well at the left; serial twofold dilutions are made in the wells to the right. In rows 1 and 2, the third well has the lowest concentration of antibiotic that shows no visible growth. In row 3, the antibiotic is ineffective at the concentrations tested because there is growth in all wells. (b, c) An automated

system for identifying clinical isolates and determining their antibiotic susceptibility. Card wells (panel c) are inoculated using the attached capillary tube. Following internal incubation, computer-scanned results are available in less than 24 hours. Photos courtesy of Marion General Hospital, Marion, Indiana (USA). (d) For the disk diffusion test, colonies from a pure culture of the pathogen are transferred to a liquid medium and mixed. (e, f) A sterile swab is dipped into the bacterial suspension and streaked evenly over the entire surface of a suitable agar medium. (g) Disks containing known

amounts of different antibiotics are placed on the inoculated agar surface. After incubation, zones of inhibition are measured, and antibiotic susceptibility is determined using a standardized chart of zone sizes. For the epsilometer test (Etest®, AB BIODISK, Solna, Sweden), a plastic strip containing an antibiotic gradient (in µg/ml) indicates the MIC at the point where the elliptical zone of inhibition meets the strip. In this example, the MIC for azithromycin (AZ) is 1.0 µg/ml.

an antimicrobial agent. When applied to the surface of an inoculated agar plate, the gradient transfers from the strip to the agar and remains stable throughout the incubation period, during which an elliptical zone of inhibition centered along the axis of the strip develops. The concentration of the antimicrobial agent (in $\mu\text{g}/\text{ml}$) is read at the point where the ellipse edge intersects the precalibrated test strip, providing a precise MIC (Figure 29.11g).

Assuming culture conditions are standardized, different antimicrobial agents can be compared to determine which is most effective against the isolated pathogen. The Clinical and Laboratory Standards Institute (www.clsi.org) is responsible for developing, establishing, and constantly updating consensus standards for antimicrobial testing. Hospital infection-control microbiologists produce and examine susceptibility data to generate periodic reports called *antibiograms*. These reports define the susceptibility of clinically isolated organisms to the antibiotics in current use. Antibiograms are used to monitor control of known pathogens, to track the emergence of new pathogens, and to identify the emergence of antibiotic resistance at the local level.

III • Immunological and Molecular Tools for Disease Diagnosis

Culture-independent clinical diagnostics, including immunological and molecular-based techniques, are critical for providing rapid and effective healthcare. The quicker an infectious disease is diagnosed, the quicker treatment can begin, and in some cases, prompt treatment is essential to save the patient.

Culture methods for some pathogens, including many viruses and some pathogenic bacteria, are not routinely available, are unreliable, or are prohibitively difficult or expensive to perform. In such cases, *growth-independent* diagnostic methods are used in clinical, reference, and research laboratories to detect specific pathogens or their products. These include a variety of immunological and molecular assays that can yield a relatively quick and reliable means of identifying individual pathogens or host exposure to pathogens in the absence of cultured organisms.

29.5 Immunoassays and Disease

Many immunoassays use antibodies specific for pathogens or their products for in vitro tests designed to detect specific infectious agents. Patient immune responses, discussed in Chapters 26 and 27, can also be monitored to obtain evidence of pathogen exposure and infection.

Serology and Antibody Titers

The study of antigen–antibody reactions in vitro is called **serology**. Serological assays detect pathogen-induced antibodies in patient serum and are the basis for a number of diagnostic tests. The *specificity* of the antibody–antigen reactions associated with serological tests allows one to pinpoint an exposure to a single pathogen, assuming the antigen used to detect antibodies is unique to the pathogen in question. Moreover, serological tests vary considerably in their *sensitivity*, that is, in the amount of antibody necessary to detect antigen. For example, passive *agglutination* reactions (see Section 29.6) are fast and easy to perform but require antibody concentrations of up to 6 nanograms (ng , 10^{-9} g) per ml. By contrast, the very sensitive but more technically demanding *enzyme immunoassay* (EIA) tests require as little as 0.1 ng of antibody per ml and can detect as little as 0.1 ng of antigen (Section 29.7).

If an individual is infected with a suspected pathogen, the immune response—antibodies to that pathogen—should become elevated. Strong evidence for infection can therefore be obtained by determining the *antibody titer* directed against antigens produced by the suspected pathogen. The **titer** is a quantitative measure of antibody level and is defined as the highest dilution (lowest concentration) of serum at which an antigen–antibody reaction is observed (Figure 29.12).

A positive antibody titer indicates previous infection or exposure to a pathogen. For pathogens rarely found in a population, such as the life-threatening hantaviruses (► Section 32.2), a single positive test for a pathogen-specific antibody may indicate active infection. In most cases, however, the mere presence of antibody does not indicate active infection. Antibody titers typically remain detectable for long periods after a previous infection has been resolved. To link an acute illness to a particular pathogen, it is essential to show a *rise*

Figure 29.12 Pattern of infection and immunity in untreated typhoid fever patients.

Body temperature indicates acute disease progression over time. Antibody titer is shown as the reciprocal of the highest serial dilution causing agglutination of *Salmonella enterica* (typhi) (► Section 33.5). The presence of bacteria in blood, feces, and urine was determined from cultures (–, no bacteria; ±, low numbers of bacteria; +, high numbers of bacteria). Bacteria clear from the blood as the antibody titer rises, whereas clearance from feces and urine requires more time. Body temperature drops to normal as the antibody titer rises.

in antibody titer in serum samples taken from a patient during the acute disease and later during the convalescent phase of the disease. Frequently, the antibody titer is low during the acute stage of the infection and rises during convalescence (Figure 29.12). A rise in antibody titer is strong circumstantial evidence that the illness is due to the suspected pathogen.

Skin Tests

A number of pathogens induce a delayed-type hypersensitivity (DTH) response mediated by Th1 cells (◀ Section 28.1). For these pathogens, skin testing may be useful to determine exposure. As an example, a commonly used skin test is the *tuberculin test*, which consists of an intradermal injection of a soluble extract from cells of *Mycobacterium tuberculosis*. A positive inflammatory reaction at the site of injection within 48 hours indicates current infection or previous exposure to (or vaccination against) *M. tuberculosis* (◀ Figure 28.4). Skin tests are routinely used to aid in diagnosis of tuberculosis, Hansen's disease (leprosy), and some fungal diseases because, as opposed to responses caused by pathogen-specific inflammatory Th1 cells, antibody responses for intracellular and fungal infections are often weak or undetectable.

If a pathogen is extremely localized, there may be little induction of a systemic immune response and no rise in antibody titer or skin test reactivity, even if the pathogen is proliferating profusely at the site of infection. A good example is the infection of urogenital mucosal surfaces with the bacterium *Neisseria gonorrhoeae*. Gonorrhea does not elicit a systemic or protective immune response, there is no serum antibody titer or skin test reactivity, and reinfection of individuals is common (▶ Section 31.13).

Monoclonal Antibodies

An expanding area of research with broad application in the diagnosis and treatment of disease is the development and use of **monoclonal antibodies (mAbs)**. In contrast to *polyclonal antibodies*, which occur as a mixture of immunoglobulins produced by many individual B cells and directed at numerous antigenic determinants on a pathogen, mAbs are derived from a B cell clone sensitized to a single antigenic determinant. Thus, an *in vitro* B cell clone culture produces monospecific mAbs that can be collected for diagnostic or therapeutic purposes. However, antibody-producing B cells are relatively short-lived and normally die within several weeks in cell culture. To produce long-lived B cell clones for commercial mAb production, antibody-producing B cells are fused with *myelomas*, tumorigenic B cells that divide and grow indefinitely (Figure 29.13). The “immortal” cell lines that result from this fusion are hybrid cells, appropriately called *hybridomas*. The hybrid cell lines share the biological properties of both fusion partners; they grow indefinitely *in vitro* and produce antibodies.

To produce a particular mAb, a mouse is immunized with the antigen of interest. Antigen-specific B cells then proliferate over several weeks and begin to produce antibodies in the mouse. B cells are then removed from the mouse and mixed with myeloma cells (Figure 29.13), but only a small number of these fuse into antibody-producing hybridomas. The hybridomas are isolated from unfused myeloma cells using a selective *HAT* medium, so called because it

contains the metabolites hypoxanthine (H) and thymidine (T), as well as the cell poison aminopterin (A). The myelomas are unable to grow in this medium because they lack an enzyme that allows them to use the H and T metabolites to circumvent the poisonous effect of aminopterin. Unfused B cells can produce the necessary enzyme, but they die after several days because they cannot divide in culture. Only the fused hybridomas, which combine the properties of both cell types, are able to both produce the necessary enzyme and grow indefinitely.

An enzyme immunoassay (Section 29.7) can be used to identify hybridomas that produce the desired mAb. From a typical fusion, several distinct clones are isolated, each making a different mAb. Once the clones of interest are identified, they can be grown either in the mouse as an antibody-producing tumor or in continuous cell culture. Antibodies can then be harvested from either source.

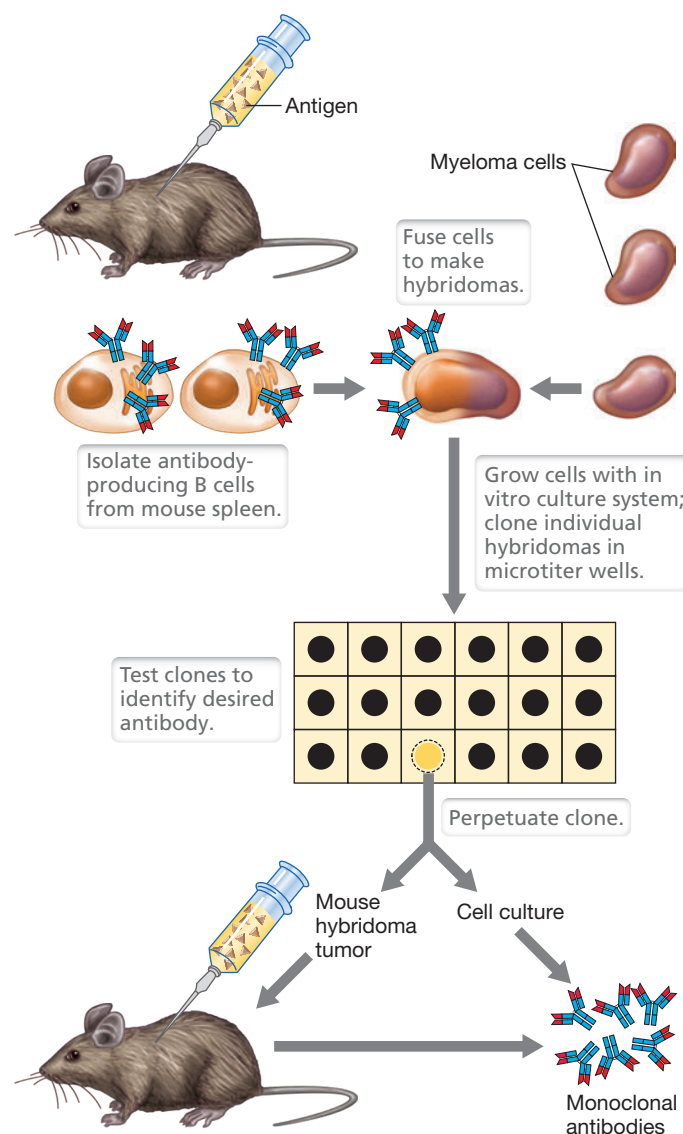

Figure 29.13 Production of monoclonal antibodies (mAbs). The hybridoma can be indefinitely cultured or passed through animals as a tumor. The hybridoma cells are stored as frozen tumor cells that can be thawed and grown in tissue culture or in a suitable animal host.

Commercial production of mAbs has replaced polyclonal antibodies for many immunodiagnostic applications because mAbs are highly specific bioreagents that can be generated with a high degree of reproducibility. Clinical diagnostic tests that use mAbs include immunological typing of bacterial pathogens, identification of cells containing foreign surface antigens (for example, a virus-infected cell), and highly specific blood and tissue typing. Because of their remarkable specificity, mAbs are also used to detect and treat human cancers (◀ Section 28.4). Malignant cells often contain tumor-specific neoantigens on their surfaces (◀ Figure 28.10), and therefore mAbs prepared against these antigens specifically target the cancer cells and can be used to deliver toxins directly to them. As discussed in Chapter 28, mAbs may also be used as *checkpoint inhibitors* to neutralize immunosuppression within the tumor microenvironment. The use of anticancer mAbs has great potential as an alternative to nonspecific chemical and radiation treatments that damage healthy cells as well as cancer cells.

29.6 Precipitation, Agglutination, and Immunofluorescence

Many clinically useful immunological reactions yield a product visible to the naked eye, such as precipitation or agglutination. Some other reactions are visualized microscopically when fluorescent dyes attached to specific antigens react with their specific antibody. We consider examples of these now.

Precipitation

Precipitation results from the interaction of a soluble antibody with a soluble antigen to form an insoluble complex. Tests can be done in liquid test tubes (or capillary tubes) or, as shown in Figure 29.14, in agarose gel. Antigens that have more than one antibody-binding epitope (◀ Section 27.2) can cross-link the bivalent antibodies that recognize them, causing a precipitate to develop from the aggregated antibody–antigen complexes. Precipitation occurs maximally when there are optimal proportions of the two reacting substances. The presence of either excess antigen or excess antibody results in the formation of soluble immune complexes (Figure 29.14).

Precipitation reactions carried out in agarose gels, called *immunodiffusion tests* (Figure 29.14 inset), are especially useful for diagnosing fungal infections, including coccidioidomycosis, histoplasmosis, blastomycosis, and paracoccidioidomycosis (▶ Section 34.2). For these tests, prepared antigen and patient antisera containing antibodies are loaded into separate wells cut into

Figure 29.14 Precipitation reactions between soluble antigen and antibody. The extent of precipitation is a function of antigen and antibody concentration. Inset photo: Precipitation in agarose gel (immunodiffusion). Well S contains antibodies to cells of *Proteus mirabilis*. Wells A, B, and C contain soluble extracts of *P. mirabilis*. An insoluble precipitation band forms where antibody and antigen concentrations are equivalent. Immunoprecipitation photo courtesy of C. Weibull, W.D. Bickel, W.T. Hashius, K.C. Milner, and E. Ribi.

the agarose gel. The reagents diffuse outward from the wells and form precipitation bands where antibody interacts with antigen in optimal proportions (Figure 29.14). Unfortunately, precipitation reactions are not very sensitive; visible precipitation requires microgram quantities of specific antibody rather than the nanogram quantities of more sensitive diagnostic tests. Consequently, with the exception of clinical diagnostic testing for fungal infections, precipitation assays are typically used only in research and reference laboratories.

Agglutination

Agglutination is a reaction between antibody and particle-bound antigen resulting in visible clumping of the particles. Agglutination tests can be done in test tubes, in microtiter plates, or by mixing reagents on glass or coated paper slides. Agglutination tests are quick to perform, inexpensive, highly specific, and reasonably sensitive, making them suitable for large-scale use in clinical applications. Standardized agglutination tests are used for the identification of blood-group antigens (on red blood cells) (Figure 29.15a), as well as pathogens and pathogen products. To determine blood groups, blood samples are mixed with either anti-A antisera or anti-B antisera and the agglutination of red blood cells, called *hemagglutination*, is assessed (Figure 29.15).

Agglutination is often assessed using rapid assays that employ small (0.8- μ m diameter) latex beads coated with a specific antigen. The beads are mixed with patient serum on a slide and incubated for a short period. If patient antibody binds the antigen on the bead surface, the milky white latex suspension will become visibly clumped, indicating a positive agglutination reaction and exposure to the pathogen.

Figure 29.15 Direct agglutination of human red blood cells: ABO blood typing. (a) A drop of whole blood was mixed with antigen-specific antisera for each reaction. The reaction on the left shows no agglutination with antibody, typical of blood type O. The reaction in the center shows the diffuse agglutination pattern indicative of blood type B. The reaction on the right shows the strong agglutination pattern with large, clumped aggregates typical of blood type A. (b) Table of expected blood typing results for people in the United States.

Latex agglutination is also used to detect bacterial surface antigens by mixing cells from a bacterial colony with antibody-coated latex beads. For example, a commercially available suspension of latex beads coated with antibodies to protein A and clumping factor, two proteins found exclusively on the surface of *Staphylococcus aureus* cells, is specific for identification of clinical isolates of *S. aureus* (Figure 29.16). Latex bead assays take less than a minute and can be used directly on clinical samples, such as the exudate from a purulent infection, often seen in cases of *S. aureus* infections. Latex bead agglutination assays have also been developed to identify other common pathogens, such as *Streptococcus pyogenes*,

Figure 29.16 Latex bead agglutination test for *Staphylococcus aureus*. In circle 1, a loopful of material from a bacterial colony was mixed in a suspension of microscopic, red latex beads coated with antibodies to two antigens found exclusively on the surface of *Staphylococcus aureus* cells. The bright red clumps indicate positive agglutination, confirming the colony as *S. aureus*. Circle 2 is a negative control showing the uniform red color expected in the absence of agglutination.

Neisseria gonorrhoeae, *Escherichia coli* O157:H7, and the fungus *Candida albicans*.

Immunofluorescence

Antibodies conjugated to fluorescent dyes can be used to detect antigens on intact cells. Such **fluorescent antibodies** are widely used for diagnostic and research applications. Fluorescent antibody staining methods can be either direct or indirect (Figure 29.17). In the *direct method*, the antibody that interacts with the surface antigen is itself covalently linked to the fluorescent dye. In the *indirect method*, the presence of a nonfluorescent primary antibody on the surface of a cell is detected by the use of a fluorescent secondary antibody directed against the nonfluorescent antibody.

Fluorescent dyes typically conjugated to antibodies include rhodamine B, which fluoresces red-orange, and fluorescein isothiocyanate, which fluoresces yellow-green (Figure 29.18). Once the fluorescent antibodies have bound to cell surface antigens, the complex can be visualized using a fluorescence microscope (◀ Figure 1.25). The cell-bound fluorescent antibodies emit their characteristic fluorescent

Figure 29.17 Fluorescent antibody methods for detection of microbial surface antigens. Note how indirect immunofluorescence requires a labeled secondary antibody that binds to the primary antibody.

suspected pathogen (Figure 29.19). For example, a presumptive diagnosis of legionellosis (Legionnaires’ disease), a form of infectious pneumonia (► Section 33.4), can be confirmed by staining biopsied lung tissue directly with fluorescent antibodies specific for cell wall antigens of *Legionella pneumophila* (Figure 29.18b), the causative agent of the disease. Immunofluorescence assays are also used to help diagnose infections from viral pathogens, such as Epstein–Barr virus (EBV) (Figure 29.19a); fungal pathogens, such as *Aspergillus* (Figure 29.19b); and gastrointestinal parasitic protozoa, such as *Giardia intestinalis* (Figure 29.19c).

- What are the advantages and disadvantages of agglutination tests versus fluorescent antibody assays? How are the latter used to identify specific cells in complex mixtures, such as blood?

29.7 Enzyme Immunoassays, Rapid Tests, and Immunoblots

Enzyme immunoassays (EIAs), which include *enzyme-linked immunosorbent assays (ELISAs)*, are immunodiagnostic tools widely used in clinical microbiology and research. EIAs are particularly useful because they are inexpensive, produce no hazardous waste, and are highly specific and sensitive; they can detect as little as 0.1 nanograms of antigen or antibody. *Rapid tests* are similar to EIAs except that results can often be reported within minutes instead of hours. Many rapid tests provide **point-of-care diagnostics** but are generally not as specific or sensitive as EIAs.

The comparatively complex and time-consuming **immunoblot (Western blot)** uses immobilized pathogen proteins as antigens to bind antibodies from patient specimens, providing highly specific evidence for pathogen exposure (see Figure 29.22). Immunoblots are often used to confirm results obtained from other serological tests, including rapid tests and EIAs.

EIAs

In EIA tests, an enzyme is covalently attached to an antigen or antibody molecule, creating an immunological tool with high specificity and sensitivity. Enzymes typically bound to antigen or antibody include peroxidase, alkaline phosphatase, and β -galactosidase, all of which interact with specific substrates to form colored reaction products that can be detected in low amounts. Four EIA formats are commonly used for evaluation of specimens for infectious disease: *direct EIA* (detects antigen), *indirect EIA* (detects antibodies), *antigen sandwich EIA* (detects antibodies using a sandwich technique), and *combination EIA* (detects both antigen and antibodies). The principal features of each platform are illustrated in Figure 29.20.

Direct EIAs are designed to detect antigens, such as virus particles in a blood or fecal sample (Figure 29.20a). Antibodies to a pathogen antigen are coated onto a support, such as a plastic microtiter plate, and the patient sample is then added. After antigen in the sample binds to the antibody, a second antibody, specific to the same antigen and coupled to an enzyme, is added. Finally, enzyme substrate

Figure 29.20 Enzyme immunoassays (EIAs). Patient samples are in color. Assay reagents are shown in black. All assays are fixed to a solid-phase support (light blue). Enzymes bound to antigen or antibody convert substrate to a colored product, shown in yellow. In each assay, the amount of colored product is proportional to the amount of pathogen-specific antibody or antigen derived from a patient sample. (a) The *direct EIA* uses immobilized pathogen-specific antibody and enzyme-labeled pathogen-specific antibody to detect pathogen antigen in patient samples such as blood. (b) The *indirect EIA* uses immobilized pathogen antigen and enzyme-labeled antibody directed to immunoglobulin to detect pathogen-specific antibodies in patient samples such as blood. (c) The *sandwich EIA* uses immobilized pathogen antigen and enzyme-labeled pathogen antigen to detect pathogen-specific antibodies in patient samples such as blood. The sandwich EIA is more sensitive than the direct or indirect EIA methods. (d) The *combination EIA* uses both the sandwich and direct assays in one platform to identify antibody and antigen in patient samples, maximizing sensitivity. In all cases, it is the enzymatic conversion of a colorless substrate to a colored product, measured spectrophotometrically, that enables quantification of specific antigen and/or antibody.

is added, and the enzyme converts the substrate to its colored product in proportion to the amount of patient antigen bound by the enzyme–antibody complex. Direct EIAs are useful for detecting bacterial exotoxins, such as those produced by *Vibrio cholerae* and *Staphylococcus aureus* (◀ Section 25.6), as well as a variety of viruses, including those that cause influenza and hepatitis.

Indirect EIAs are used to detect antibodies to pathogens in body fluids (Figure 29.20b). The indirect test starts with pathogen antigen immobilized on a supportive matrix. Patient serum is added, and antibodies (if present) bind to the antigen. Next, an antibody–enzyme complex specific for the patient antibodies is added. Finally, the addition of the enzyme substrate results in the development of a colored product that is proportional to the concentration of patient antibody in the sample. Indirect EIAs are used to detect serum antibodies to a wide variety of bacterial, viral, and eukaryotic pathogens.

The antigen sandwich EIA also detects antibodies to pathogens in body fluids (Figure 29.20c). The sandwich test starts with pathogen antigen immobilized on a support. Patient serum is added, and antibodies (if present) bind to the antigen. Next, the same antigen coupled to enzyme is added, followed by the addition of the enzyme substrate, resulting in the development of colored product that is proportional to the concentration of patient antibody in the sample. This method is especially sensitive because it detects pathogen-specific antibody irrespective of antibody class. This method is often used for HIV screening (the third-generation HIV test) because it can detect IgM produced during the primary immune response to HIV as soon as four weeks after infection. By contrast, most indirect EIAs use anti-IgG as the enzyme-conjugated antibody, delaying observation of antibodies to HIV until the secondary antibody response at least five weeks after infection (◀ Figure 27.10).

The combination EIA, shown in Figure 29.20d, makes use of a direct EIA to detect pathogen antigen and the sandwich method to detect pathogen-specific antibodies, both on a single matrix. This method, used for a fourth-generation HIV test, is more sensitive than the third-generation sandwich test; antigen can be detected as little as 2.5 weeks after HIV infection, reducing the time to treatment.

Rapid Tests

Rapid immunoassay procedures use reagents adsorbed to a fixed support material, such as paper strips or plastic membranes. These point-of-care tests cause a color change on the strip within minutes and serve as rapid diagnostic aids for a variety of infectious diseases, including HIV/AIDS.

For most rapid tests, a body fluid (generally urine, blood, saliva, or sputum) is applied to a sample well in a reagent–support matrix. To detect antigen in patient samples, for example to determine infection by *Streptococcus pyogenes* (strep throat), the matrix contains soluble antibodies that are specific to the antigen in question and conjugated to a colored molecule called a *chromophore* (Figure 29.21). As the liquid sample diffuses through the matrix, patient antigens (if present) bind the chromophore-labeled antibodies. Capillary action pulls each labeled antigen–antibody complex through the matrix, where it contacts a single line of fixed antibodies. The labeled antigen–antibody complex binds a fixed antibody and becomes immobilized. As the concentration of labeled complex increases, the chromophore becomes visible as a line of color along the fixed antibody, indicating

(a)

(b)

Figure 29.21 Rapid tests. (a) A patient specimen containing a mixture of antigens is applied to the sample well of a support matrix. Capillary action pulls the liquid sample through the matrix, and specific antigen (if present) binds soluble, chromophore-labeled antibodies. The labeled antigen–antibody complexes diffuse through the matrix and bind a line of fixed antibodies. A colored line becomes visible as the concentration of labeled complex builds, indicating a positive test for the antigen. Unbound labeled antibodies bind a second line of fixed antibody as a control. (b) From left to right, rapid tests for respiratory syncytial virus (RSV), group A streptococci (GAS), and influenza A/B. The RSV test and the left GAS test show a test line, indicating positive reactions. The right GAS test and the influenza A/B test show only a control line, indicating negative reactions. Photo courtesy of Marion General Hospital, Marion, Indiana (USA).

a positive test for the antigen. Labeled antibodies not bound by antigen concentrate at a second line of fixed antibodies that are specific to the labeled antibody rather than the antigen, thus forming a second colored line that serves as the control.

These tests are valuable for point-of-care analysis and provide rapid diagnostic results that can be reported almost immediately, avoiding the need for delays in patient care or for follow-up visits to obtain test results. The drawback to rapid tests, however, is that they are often less specific or less sensitive than more elaborate assays for the same pathogens. As a result, rapid tests often need to be confirmed by EIA or other tests, such as the immunoblot, discussed next.

Immunoblots

Immunoblot methodology requires the *separation* of proteins on a polyacrylamide gel, the *transfer* (blotting) of the proteins from the gel to a nitrocellulose or nylon membrane, and finally, the *identification* of the proteins using specific antibodies (**Figure 29.22a**). The HIV immunoblot (**Figure 29.22b**) can be used to accurately diagnose HIV infection, but although it is highly specific, it is generally not used as a screening tool because it is less sensitive, more time consuming, and more expensive than the HIV EIA. However, because the HIV EIA occasionally yields false-positive results, the immunoblot method is often used to confirm positive EIA tests. The HIV immunoblot procedure is similar to immunoblot methods used to diagnose infection by other pathogens. In general, immunoblots are used to detect pathogen-specific antibody in patient samples.

To perform the HIV immunoblot, membrane strips containing fixed HIV proteins are incubated with the patient serum sample. If the sample is HIV-positive, patient antibodies will bind to the HIV proteins on the membrane. To detect whether antibodies from the serum sample have bound to HIV antigens, a detecting antibody, anti-human IgG conjugated to an enzyme, is added to the strips. If

(b) The molecules p24 (capsid protein) and gp41 (envelope glycoprotein) are diagnostic for HIV. Lane 1, positive control serum (from known AIDS patients); lane 2, negative control serum (from healthy volunteer); lane 3, strong positive from patient sample; lane 4, weak positive from patient sample; lane 5, reagent blank to check for background binding.

the detecting antibody binds, the activity of the conjugated enzyme, after addition of substrate, will form a colored band on the strip at the site of antibody binding. The patient is HIV-positive if the positions of the bands in the patient sample match those of a positive control; a negative control serum is also analyzed and must show no bands (Figure 29.22b). As the test is mostly used to confirm positive EIA results for HIV (or correct false positives), variations in band intensity do not affect interpretation of the results.

29.8 Nucleic Acid–Based Clinical Assays

In Section 12.1 we discussed how the polymerase chain reaction (PCR) amplifies nucleic acids, forming multiple copies of target sequences. PCR techniques can employ primers for a pathogen-specific gene to examine DNA derived from suspected infected tissue, even in the absence of an observable or culturable pathogen. As a result, PCR-based tests are widely used in the clinical lab for pathogen

identification, and they are particularly useful for identifying viruses and other intracellular pathogens that are difficult or impossible to culture using current techniques. PCR methods are extremely sensitive and do not depend on pathogen isolation or growth, and no detection of an immune response to the pathogen is required. Instead, microbe-specific nucleic acid sequences are detected in the assays.

Nucleic Acid Hybridization and Amplification

Nucleic acid hybridization (◀ Section 12.1) is the central theme of nucleic acid–based molecular methods. In clinical medicine, hybridization methods are employed to identify specific pathogens in patient samples by using unique nucleic acid *probes* to detect the presence of specific DNA sequences. Nucleic acid probes are single-stranded DNA molecules having a sequence complementary to that of a gene of interest. A DNA probe oligonucleotide may be less than 100 base pairs or up to several kilobases in length. If a microbe from a clinical specimen contains DNA or RNA sequences complementary to the probe, the probe will hybridize (following appropriate sample preparation to yield single-stranded target molecules), forming a double-stranded molecule (Figure 29.23). To detect the hybridization reaction, the probe is labeled with a reporter molecule, which is usually a fluorescent compound, but radioisotopes or enzymes may also be used.

To carry out a probe assay, samples are treated with strong alkali, usually sodium hydroxide (NaOH), to lyse the cells and partially denature the pathogen DNA, forming single-stranded DNA

Figure 29.23 Nucleic acid probe methodology in clinical diagnostics. (a) Membrane filter assay. The reporter can be a radioisotope, a fluorescent dye, or an enzyme. (b) Dipstick assay. Dual reporter and capture probes are used. The capture probe contains a poly(A) tail that hybridizes to a poly(T) oligonucleotide affixed to the dipstick. Binding of the target DNA–reporter complex is usually detected as a visible color change.

molecules (Figure 29.23). Incubation at an appropriate temperature facilitates formation of a stable duplex between target DNA and probe DNA. The extent of hybridization is measured using the reporter molecule attached to the probe. Some assays use two-component probes that function as both a *reporter* probe and a *capture* probe; the addition of a sequence tag allows the hybridized molecule to be affixed to a matrix, usually a dipstick, for detection purposes (Figure 29.23b).

Nucleic acid hybridization also plays a critical role in the various PCR-based techniques used to amplify target DNA or RNA molecules. PCR analysis begins with the extraction of DNA or RNA from the sample to be tested. Next, the nucleic acid must be amplified using appropriate gene-specific nucleic acid *primers*. These short oligonucleotides (typically 15–27 base pairs in length) are not used as probes but instead function to jump-start DNA polymerase during PCR amplification of pathogen-specific genes. Lastly, the amplified nucleic acid product (the *amplicon*) is visualized, a procedure that may involve gel electrophoresis or, more often in clinical laboratories, fluorescence. The presence of the appropriate amplified gene segment confirms the presence of the pathogen.

Quantitative PCR and Reverse Transcription PCR

Many clinical PCR tests employ *quantitative real-time PCR (qPCR)*. This process uses fluorescent probes to label PCR amplicons, thereby allowing the accumulation of target DNA to be visualized. Because probe fluorescence increases upon binding to DNA, the level of fluorescence increases proportionally as the target DNA is amplified. The fluorescent probes may be either nonspecific or specific for the target DNA. For example, the dye SYBR Green binds *nonspecifically* to double-stranded DNA and fluoresces only when bound. When added to the PCR mixture, SYBR Green fluorescence indicates the presence of double-stranded DNA produced by the amplification process (Figure 29.24a). By contrast, *gene-specific* fluorescent probes, made by attaching a fluorescent dye to a short DNA probe specific to a target sequence, fluoresce only when double-stranded DNA of the correct sequence accumulates.

Because qPCR amplification can be monitored continuously via fluorescence, visualization by gel electrophoresis is not necessary to confirm amplification. Using modern instrumentation, such as that shown in Figure 29.24b, detection of a gene diagnostic for a particular pathogen in a clinical sample may be performed in about 2 hours. Moreover, by monitoring the *rate* of fluorescence increase in the PCR reaction, it is possible to accurately determine the amount of target DNA present in the original sample (Figure 29.24a). Thus, qPCR can be used to assess the abundance of a pathogen in a sample by quantifying a gene characteristic for that particular organism.

Another variation of basic PCR is *reverse transcription PCR (RT-PCR)*, which uses pathogen-specific RNA to produce complementary DNA (cDNA) directly from patient samples (◀ Section 12.1). This technology is especially useful for the detection of RNA viruses, including retroviruses such as HIV. The first step in RT-PCR is to use the enzyme reverse transcriptase to make a cDNA copy of an RNA sample. PCR is then used to amplify the cDNA. By isolating RNA in a sample and making cDNA copies of the corresponding gene(s), one can employ qPCR to monitor the expression of a particular gene from a pathogen. The amplified DNA can then be sequenced or probed for identification.

(a)

(b)

Figure 29.24 Quantitative real-time polymerase chain reaction (qPCR) for clinical diagnostics. (a) DNA extracted from a gram-negative bacterial culture was monitored for expression of 16S rRNA (curve A) and *npt* (curve B), a kanamycin resistance marker, using gene-specific primers. The fluorescent dye SYBR Green was added to the PCR mixture and used to visualize amplified DNA as it formed. The curve on the left (A) had 0.15 fluorescence units after 15 cycles, while the curve on the right (B) had 0.15 fluorescence units after 22 cycles, indicating that the 16S rRNA had a higher abundance of template DNA than *npt* in this strain. (b) qPCR instrumentation in a clinical laboratory. The single-use cartridges contain all necessary components for the qPCR reaction, including group-specific primers and fluorescent dyes, and pathogens can be identified in less than 2 hours. The cartridge on the left is specific for detection of group B streptococci (*Streptococcus agalactiae*). Photos courtesy of Marion General Hospital, Marion, Indiana (USA).

Qualitative PCR

Some diagnostic tests based on the qPCR format use a slightly different amplification protocol and an additional step to identify pathogen-associated genes. This method, called *qualitative PCR*, uses labeled hybridization primers that are incorporated into an amplicon product of a qPCR reaction.

In the example shown in Figure 29.25, the hybridization probes are targeted to the DNA *pol* gene of herpes simplex 1 and 2 viruses (HSV-1 and HSV-2) (◀ Section 11.7). The amplicon is detected using two distinct hybridization probes labeled with fluorescent dyes. The

Figure 29.25 Qualitative PCR for the *pol* gene of HSV-1 (herpes simplex 1 virus) and HSV-2. DNA from a patient sample was assayed for the *pol* gene of both HSV-1 and HSV-2 following quantitative PCR (qPCR). Two fluorescent-labeled probes hybridize with an internal sequence of the amplified fragment of each viral genome during the PCR cycle. After hybridization to the template DNA, the probes are excited by a light source, and their fluorescence is measured. After the PCR cycle, each virus shows a distinct DNA melting curve. The melting profile in the patient sample (red) corresponds to the HSV-2 standard (green), indicating infection with HSV-2.

probes hybridize to an internal sequence of the amplified fragment during the annealing phase of the PCR cycle. After hybridization to the template DNA, the probes are excited by a light source in the PCR instrument. The emitted fluorescence is then measured, and, after the PCR cycle, a melting curve analysis is performed to differentiate between samples positive for HSV-1 and HSV-2. Because of nucleotide polymorphisms between the DNA *pol* genes of the two virus subtypes, the melting curve for HSV-1 is distinct from that of HSV-2 (Figure 29.25). The results are compared to internal assay control reactions, and an unambiguous diagnosis of viral infection can be obtained within hours.

With a solid foundation of clinical diagnostics in hand, we move on in Chapter 30 to explore how infectious diseases are transmitted, tracked, and controlled in the fast-moving field of *epidemiology*.

Check Your Understanding

- What advantage(s) does nucleic acid amplification have over standard culture methods for identification of microorganisms? What are the disadvantages?
- How do quantitative PCR (qPCR) and qualitative PCR differ?

CHAPTER REVIEW

I • Microbiology and the Healthcare Environment

- 29.1** Clinical laboratory safety requires training and planning to prevent contamination and possible infection of laboratory workers. Specific precautions and procedures proportional to the risk of infection by a given agent, designated by bio-safety levels (BSL), must be in place to handle contaminated materials and patient specimens.

Q How are most laboratory-associated infections contracted? What action can be taken to prevent laboratory infections?

- 29.2** Patients in healthcare facilities are unusually susceptible to infectious disease because of their compromised health and potential exposure to various pathogens in the facilities. Many healthcare-associated infections are caused by drug-resistant pathogens.

Q What are healthcare-associated infections (HAI) and how are they acquired? What problems can they cause?

II • Isolating and Characterizing Infectious Microorganisms

- 29.3** Appropriate sampling, observation, and culture techniques are necessary to isolate and identify potential pathogens. The selection of techniques requires knowledge of the ecology, physiology, and metabolism of suspected pathogens. Most pathogens exhibit unique metabolic patterns when

grown on specialized selective and differential media. Growth-dependent patterns provide information helpful for unambiguous pathogen identification.

Q In order to ensure accurate diagnosis, what measures should be taken during the collection of specimens and while detecting and culturing pathogens?

- 29.4** Pathogens isolated from clinical samples are often tested for antibiotic susceptibility to ensure appropriate antibiotic therapy. Testing is based on the minimum inhibitory concentration of an agent necessary to completely inhibit growth of a pathogen.

Q How does the traditional method of determining minimum inhibitory concentration (MIC) compare to current practice?

III • Immunological and Molecular Tools for Disease Diagnosis

- 29.5** An immune response is a natural outcome of infection. Specific immune responses characterized by a rise in antibody titers and positive T cell-mediated skin tests can be used to provide evidence of infections and to monitor convalescence. Monoclonal antibodies reproducibly provide specificity for a wide range of diagnostic and therapeutic purposes.

Q Why does antibody titer rise after infection? Is a high antibody titer indicative of an ongoing infection? Explain. Why is it necessary to obtain an acute and a convalescent blood sample to monitor infections?

29.6 Precipitation and agglutination reactions produce visible results involving antigen–antibody interactions. Fluorescent antibodies are used for quick, accurate identification of pathogens and other antigenic substances in tissue samples, blood, and other complex mixtures. Fluorescent antibody-based methods can be used for identification of a variety of microbial cell types.

Q Why are agglutination tests so widely used in clinical diagnostics? How are fluorescent antibodies used to diagnose diseases? What advantages do immunofluorescent techniques have over traditional culturing?

29.7 Enzyme immunoassays (EIAs), rapid tests, and immunoblots are sensitive and specific immunological assays. These tests can be engineered to detect either antibody or antigen for diagnosis of infections by any of a large number of pathogens.

Q EIAs are extremely sensitive diagnostic tools. Why, then, is the immunoblot (Western blot) procedure used to confirm screening tests that are positive for human immunodeficiency virus (HIV)?

29.8 Nucleic acid amplification (PCR) methods are applied as extremely specific diagnostic tools used for a large number of pathogens. Quantitative PCR (qPCR) and qualitative PCR techniques provide quantification and identification of pathogens, and reverse transcription PCR (RT-PCR) is especially useful for detecting RNA viruses.

Q Distinguish between quantitative and qualitative PCR. How does qualitative PCR expand upon the qPCR technique?

APPLICATION QUESTIONS

1. Define the procedures you would use to isolate and identify a new pathogen. Keep in mind Koch's postulates (◀ Figure 1.33) as you form your answer. Be sure to include growth-dependent assays, immunoassays, and molecular assays. Which of your assays could be adapted to be used as a routine test for rapid clinical diagnosis?
2. Imagine yourself as a clinical microbiologist with all of the diagnostic tools described in this chapter available for your

analyses. Which tool(s) would you use (and why) for the following cases? (1) A patient has a life-threatening infection caused by a difficult-to-culture bacterium, and treatment of the infection is absolutely dependent on an extremely rapid identification of the pathogen. (2) A patient has a less severe bacterial infection with a pathogen that is easily culturable and treatable.

CHAPTER GLOSSARY

Agglutination a reaction between antibody and particle-bound antigen resulting in visible clumping of the particles

Differential media growth media that allow identification of microorganisms based on phenotypic properties

Enzyme immunoassay (EIA) a test that uses antibodies or antigens linked to enzymes to detect antigens or antibodies in body fluids

Fluorescent antibody an antibody molecule covalently modified with a fluorescent dye that makes the antibody visible under fluorescent light

Healthcare-associated infection (HAI) an infection acquired by a patient in a health-care facility, particularly during a stay in the facility. Also called a *nosocomial infection*.

Immunoblot (Western blot) the use of labeled antibodies to detect specific proteins after separation by electrophoresis and transfer to a membrane

Minimum inhibitory concentration

(MIC) the smallest amount of an antimicrobial substance that prevents growth of the target microorganism

Monoclonal antibody (mAb) a single type of antibody made by a single B cell hybridoma clone

Point-of-care diagnostics clinical testing that produces a clear medical result and a treatment plan within the same clinical visit

Precipitation a reaction between antibody and a soluble antigen resulting in a visible, insoluble complex

Selective media culture media that allow the growth of certain organisms while inhibiting the growth of others through one or more added media components

Sensitivity the lowest amount of antigen that can be detected by a diagnostic test

Serology the study of antigen–antibody reactions in vitro

Specificity the ability of a diagnostic test to identify a specific pathogen

Titer the number of individual particles of a substance, such as antibodies or infectious virions, per unit volume of a solution

- III Emerging Infectious Diseases, Pandemics, and Other Threats 976

A New Urgent Threat Is Emerging in Public Health Microbiology

For several years now, epidemiologists have been tracking the emergence of a new, highly invasive and deadly pathogen, but it is neither a bacterium nor a virus. This pathogenic microbe is a nosocomial (healthcare-associated) fungus, and the U.S. Centers for Disease Control and Prevention (CDC) has recently added it to a list of microorganisms considered to be “urgent threats.” The new fungal pathogen, first described in 2009, is a yeast called *Candida auris*, a relative of the opportunistic yeast *Candida albicans*, which causes vaginal candidiasis and oral thrush.

Since its initial description, cases of *C. auris* infection have been documented in hospitals on every continent but Antarctica. Systemic infection by *C. auris* results in a mortality rate approaching 60%, with immunocompromised patients comprising the largest fraction of these fatalities. One major *C. auris* outbreak in the United Kingdom occurred among intensive care unit patients. In this incident, the yeast was transmitted between patients through multiuse thermometers that measure temperature in the armpit. Despite staff’s adherence to established protocols to disinfect the

equipment between uses, a shocking 86% of patients that had contact with the thermometers subsequently developed *C. auris* infection.

Invasive infections by *C. albicans* often result from neutropenia (decreased numbers of neutrophils). However, studies have shown that *C. auris* infection frequently occurs even in the presence of normal numbers of neutrophils, suggesting that innate defenses do not adequately contain the pathogen. In the presence of both *C. albicans* (red cells, photo) and *C. auris* (blue), neutrophils (green) readily engaged and killed *C. albicans* (open arrows) but ignored *C. auris* (closed arrows). This fascinating but disconcerting finding suggests that *C. auris* possesses an efficient mechanism of phagocyte evasion. Considering that *C. auris* is also resistant to several antifungal drugs, healthcare providers and epidemiologists may have a long struggle ahead of them to control this emerging pathogen.

Source: Nett, J.E. 2019. *Candida auris*: An emerging pathogen “incognito”? *PLoS Pathog.* 15(4): e1007638. doi:10.1371/journal.ppat.1007638.

Beginning with this chapter and to the end of the book, we focus on the nature and diversity of infectious diseases. Everything we have learned up to this point—cell structure, metabolism, growth, genetics, and genomics; microbial evolution, diversity, and ecology; and host–microbe relationships and the immune response—will help us better understand the disease strategies and exploitable weaknesses of infectious microbial agents.

As a prelude to our coverage of the clinical aspects of infectious diseases in the following four chapters, we explore the “big picture” of how infectious diseases flow through populations. **Epidemiology** is the study of the occurrence, distribution, and determinants of health and disease in populations and is intertwined with **public health**, the health of the population as a whole. Although in developed countries infectious diseases are not leading causes of death, in developing countries infectious diseases can account for nearly half of all deaths. Hence, identifying and solving problems associated with infectious disease transmission is a major goal of the epidemiologist.

I • Principles of Epidemiology

Focused on the distribution, prevalence, and transmission of disease, epidemiology is foundational to the health and prosperity of the human population on a global scale. Moreover, disease tracking often reveals patterns that improve disease treatment.

In this first part of the chapter we consider the principles of epidemiology and define key terms in the lexicon of the epidemiologist.

30.1 The Language of Epidemiology

The epidemiologist traces the spread of a disease to identify its origin and mode of transmission in a population. The population might be all people in a certain city, country, or region, or it could be the entire human population. Alternatively, the population under study could be a particular demographic within a larger population, such as only males or only those of a specific race or age group. Raw data are gathered from disease-reporting networks such as city, county, state, and national public health departments, clinical records, and patient interviews.

A major job of the epidemiologist is to carry out **disease surveillance**—the observation, recognition, and reporting of diseases as they occur—and then analyze the data provided by local and national health authorities to reveal trends and signals of disease outbreaks. The epidemiologist thus stands in contrast to the clinical health provider—the one who actually treats the infected patient. However, in order to both track a disease and predict its spread in a population, the epidemiologist must integrate clinical results and surveillance data to formulate effective public health measures for disease control.

Disease Incidence and Prevalence

The epidemiologist often uses the words *incidence* and *prevalence* when discussing infectious diseases. The **incidence** of a particular disease is the *number of new cases* in a population in a given time period (Figure 30.1). For example, in 2016 there were 38,700 new cases of HIV infection in the United States, for an incidence of 12 new cases

Figure 30.1 The concepts of disease incidence and disease prevalence. Disease incidence is a rate function and is defined as the number of new cases over a given time period (day[s], week, month, etc.); incidence is an indicator of infection risk. Disease prevalence is the total number of diseased individuals at some time point and is a snapshot of the extent of a disease in a population at any given time.

per 100,000 people per year. The **prevalence** of a given disease is the *total number of new and existing disease cases* in a population in a given time period (Figure 30.1). For example, within the United States there were 1,008,929 persons living with HIV/AIDS at the end of 2016. Expressed another way, the prevalence of HIV/AIDS in the United States was about 317 cases per 100,000 persons in 2016.

Essentially a *rate* measurement, disease incidence can be used to predict the *risk* of disease for an individual in a defined population within a specific time period. By contrast, prevalence measures the total disease burden in a population and can be thought of as a “snapshot” of the disease at a specific instant (Figure 30.1). The incidence and prevalence of disease are also major indicators of the public health of a population.

The Scope of Disease

Other common epidemiological terms speak to the scope of a disease. A disease is an **epidemic** when it simultaneously infects an unusually high number of individuals in a population; a **pandemic** is a widespread, usually global epidemic. By contrast, an **endemic disease** is one that is constantly present—typically in low numbers—in a population (Figure 30.2). An endemic disease implies that the pathogen may not be highly virulent or that the majority of individuals in the population may be immune, resulting in low but persistent numbers of cases. Individuals infected with a pathogen that causes an endemic disease are **reservoirs** of infection, a source of infectious agents from which susceptible individuals may be infected.

Sporadic cases of a disease occur one at a time in geographically separated areas, suggesting that the cases are not related. A disease

Figure 30.2 Endemic, epidemic, and pandemic disease. Each dot represents a disease case or outbreak. (a) Endemic diseases are present in the population in specific geographical areas. (b) Epidemic diseases show high incidence in a wider area, usually developing from an endemic focus. (c) Pandemic diseases are distributed intercontinentally.

outbreak, on the other hand, is the appearance of a large number of cases in a short time in an area previously experiencing only sporadic or endemic disease. Diseased individuals that show no symptoms or only mild symptoms are said to have *subclinical infections*. Subclinically infected individuals are frequently **carriers** of the particular pathogen, with the pathogen reproducing within them and being shed into the environment where it can infect others. Finally, the term **virulence**, often used in epidemiological parlance, is a measure of the *relative ability* of a pathogen to cause disease. Some pathogens are highly virulent while others are only weakly so (◀ Section 25.3).

Stages of Disease

A well-adapted pathogen lives in balance with its host, taking what it needs for existence and causing only minimal harm. Such pathogens may cause **chronic infections** (long-term infections) in the host. When there is a balance between host and pathogen, both host and pathogen survive. Tuberculosis (▶ Section 31.4) is a good example of a chronic infection. On the other hand, a host whose resistance is compromised because of factors such as poor diet, age, and other stressors can be harmed or even killed; for example, a chronic tuberculosis infection can eventually kill the host.

New pathogens occasionally emerge to which specific populations or even an entire species has not developed resistance. Such emerging pathogens often cause **acute infections**, characterized by rapid and dramatic disease onset and a relatively quick return to health. Influenza caused by a new strain of influenza virus (▶ Section 31.8) would be an example of an acute infection, as would many other infectious diseases that show a rapid onset and recovery, such as various food infections and food poisonings (Chapter 33), or even the common cold (▶ Section 31.7). The progression of clinical symptoms for an acute infectious disease can be divided into stages, and the terms used to describe these stages are also part of the epidemiologist's lexicon:

1. **Infection:** The organism invades, colonizes, and grows in the host.

2. **Incubation period:** Some time always passes between infection and the appearance of disease signs and symptoms. Some diseases, like influenza, have very short incubation periods, measured in days; others, like AIDS, have longer incubations, sometimes extending for years. The incubation period for a given disease is determined by the inoculum size, the virulence and life cycle of the pathogen, and the resistance of the host. At the end of the incubation period, the first signs and symptoms, for example, a mild cough and a feeling of general fatigue in the case of an ensuing cold, usually appear.
3. **Acute period:** The disease is at its height, with overt symptoms and signs such as fever and chills.
4. **Decline period:** Disease signs and symptoms subside. As fever subsides, usually following a period of intense sweating, a feeling of well-being develops. The decline period may be rapid (within one day), in which case decline occurs by *crisis*, or it may be slower, extending over several days, in which case decline occurs by *lysis*.
5. **Convalescent period:** The patient regains strength and returns to the normal healthy state.

After the acute period, the immune mechanisms of the host (Chapters 26 and 27) become increasingly important for complete recovery from the disease.

Mortality, Morbidity, and DALY

The terms *morbidity* and *mortality* are commonly used in epidemiology. **Mortality** is the incidence of *death* in a population. Infectious diseases were the major causes of death worldwide in 1900, but they are now less prevalent in developed countries. Noninfectious “lifestyle” diseases such as heart disease and cancer are now much more prevalent in developed regions and cause higher mortality than do infectious diseases (◀ Figure 1.13). However, this could change rapidly if public health measures were to break down. Worldwide, and especially in developing countries, infectious diseases are still major causes of mortality (Table 30.1 and see Figure 30.9).

Morbidity is the incidence of *disease* in a population and includes both fatal and nonfatal diseases. Morbidity statistics indicate the public health of a population more precisely than mortality statistics because many diseases have relatively low mortality. Put another way, the major causes of *illness* are quite different from the major causes of *death*. For example, high-morbidity infectious diseases include acute respiratory diseases such as the common cold and acute digestive disorders. However, seldom do these diseases cause death in populations living in developed countries. Thus, both of these diseases have high morbidity, but low mortality. On the other hand, Ebola virus infects relatively few people worldwide every year, but the mortality in some outbreaks approaches 70% and averaged 40% in the West African Ebola outbreak of 2013–2015. Thus, Ebola has low morbidity, but high mortality.

Epidemiologists tend to focus on morbidity and mortality statistics as a means of ranking the severity of pathogens and tracking disease trends. However, illness and death are not the only outcomes of an infectious disease. Lost among these statistics is the reduction in life quality and productivity due to a disease. The **disability-adjusted life year (DALY)** is a quantitative measure of disease burden and is defined as the cumulative number of years lost due to an

TABLE 30.1 Worldwide deaths due to infectious diseases ^a		
Disease	Deaths (% of deaths from all infectious diseases)	Causative agent(s)
Respiratory infections ^b	26	Bacteria, viruses, fungi
Diarrheal diseases	12	Bacteria, viruses
Tuberculosis ^c	11	Bacterium
Acquired immunodeficiency syndrome (AIDS)	9	Virus
Malaria	4	Protist
Meningitis, bacterial ^c	2	Bacteria
Encephalitis	1	Bacteria, viruses, fungi
Hepatitis (all types) ^d	1	Viruses
Syphilis	1	Bacterium
Measles ^c	1	Virus
Other communicable diseases	32	Various agents

^aData show the ten leading causes of death due to infectious diseases in 2016. Worldwide there were nearly 57 million total deaths, and 20% of these were from infectious diseases, mostly in developing countries. In the United States in 2016, deaths from infectious diseases were about 4% of total deaths (influenza, pneumonia and septicemia were leading causes). Data adapted from data published by the World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC), Atlanta, Georgia, USA.

^bFor some acute respiratory agents, such as influenza viruses and *Streptococcus pneumoniae*, there are effective vaccines; for others, such as colds, there are no vaccines.

^cDiseases for which effective vaccines are available.

^dVaccines are available for hepatitis A virus and hepatitis B virus. There are currently no vaccines for other hepatitis agents, but a drug is available that can cure hepatitis C infections.

illness itself, a disability due to an illness (whether an infectious disease or not), or premature death.

The leading causes of death are not the leading causes of disability; about one-third of all disability years lost are due to psychiatric and neurological conditions. But many infectious diseases cause chronic disability and thus such data are important measures of the overall burden of disease. This is especially true of a series of *neglected tropical diseases*, a group of infectious diseases found mainly in tropical countries that are major disablers rather than killers. These include in particular parasitic worm infections such as hookworm, filariases, and schistosomiasis (► Section 34.7). Hundreds of millions of people suffer from these infections worldwide, and although some die, most do not. However, life quality and longevity of survivors is often greatly diminished, and DALY numbers attempt to quantify this frequently overlooked but nevertheless important aspect of epidemiological statistics.

With some of the epidemiologist’s common terminology in mind, we are now able to move on to consider how infectious diseases spread (or do not spread) in susceptible populations.

Check Your Understanding

- Why do epidemiologists acquire population-based data about infectious diseases?
- Distinguish between an endemic disease, an epidemic disease, and a pandemic disease.
- Which is more severe, a disease with a high mortality or one with a high morbidity? What is a DALY?

30.2 The Host Community

The colonization of a susceptible host population by a pathogen may lead to rapid transmission to uninfected hosts, widespread infections, and an epidemic. As the host population develops resistance, however, the spread of the pathogen is checked, and eventually a balance is reached in which host and pathogen populations reach a state of equilibrium. In an extreme case, failure to reach equilibrium could result in death and eventual extinction of the host species. If the pathogen has no other host, then the extinction of the host also results in extinction of the pathogen. The evolutionary success of a pathogen thus depends on its ability to establish an equilibrium with its host rather than destroy the host population altogether. In most cases, the evolution of the host and the pathogen affect one another; that is, the host and pathogen *coevolve*.

Coevolution of a Host and a Pathogen

A classic example of host and pathogen coevolution is a case where myxoma virus was intentionally introduced to control an exploding wild rabbit population in Australia. The virus, spread by the bite of mosquitoes and also from animal to animal by direct contact, is extremely virulent for rabbits and causes fatal infections in susceptible animals. Within several months, the introduced epidemic had spread over a large area, rising to peak incidence in the summer when the mosquito vectors were present, and then declining in the winter as mosquitoes disappeared. In this experiment, over 95% of infected rabbits died during the first year, but within six years, rabbit mortality dropped to about 30%, indicating that the resistance of the wild rabbit population to the virus had increased dramatically (Figure 30.3). When viruses isolated from these wild rabbits were used to infect laboratory rabbits that had not previously been exposed to the virus, the virus could be seen to have lost virulence over the

Figure 30.3 Myxoma virus and host coevolution. Myxoma virus was introduced into Australia to control the wild rabbit population. Virus virulence was measured as the average mortality in laboratory rabbits for infection with myxoma virus recovered from the field each year. Rabbit mortality was determined by removing young wild rabbits from dens and infecting them with a viral strain that killed 90–95% of control laboratory rabbits.

six-year period. This was further confirmed by the resistance observed in newborn wild rabbits exposed to the virus. Within three years, viral virulence decreased by about 80% and maintained this diminished level of virulence (Figure 30.3). Thus, within just a few years, the rabbit population had evolved to reach an equilibrium with the pathogen.

For pathogens that do not exhibit host-to-host transmission, there is no selection for decreased virulence to support mutual coexistence, as was seen in the rabbit myxoma virus experiment. An example of this is *Clostridium tetani*, a common soil bacterium that causes tetanus when accidentally introduced into flesh through a penetrating wound (◀ Section 25.6 and ▶ Section 32.9). Vectorborne pathogens transmitted solely by the bite of ticks or other arthropods, such as in spotted fever rickettsiosis (Rocky Mountain spotted fever, ▶ Section 32.3), are also under no evolutionary pressure to spare the human host. As long as the vector is only a *carrier* of the pathogen and does not contract the disease itself, there is no selection for weakened strains of the pathogen and thus the pathogen can maintain a high level of virulence.

Herd Immunity

Spread of an infectious disease through a highly susceptible population is typically much different than through a population where many, or even just some, potential hosts are immune, either from a previous natural infection with the same pathogen or by artificial means through vaccination. If a high enough proportion of the individuals in a population are immune to a pathogen, then the population as a whole can be protected from an epidemic, resulting in a collective level of resistance to infection called **herd immunity** (Figure 30.4).

The concept of herd immunity is easy to understand. In essence, what herd immunity amounts to is a breakage in the chain of pathogen transmission from one susceptible host to another because most hosts in the population are immune (Figure 30.4). Herd immunity is not a fixed number, and the assessment of herd immunity is important for understanding the development of epidemics. The more highly infectious a pathogen, or the longer its period of infectivity, the greater the proportion of immune individuals necessary to prevent epidemic disease spread. For a highly infectious disease such as measles, 90–95% of the population must be immune to confer herd immunity (see Table 30.3). By contrast, a lower proportion of immune individuals can prevent an epidemic of a less infectious agent or one with only a brief period of infectivity. Mumps virus, which is less infectious than measles virus, exhibits this pattern. In the absence of immunity, even poorly infectious agents can be transmitted from person to person if susceptible hosts have repeated or constant contact with an infected individual. This is the case for the transmission of H5N1 avian influenza among humans (Section 30.8).

Check Your Understanding

- Explain coevolution of host and pathogen. Cite a specific example.
- How does herd immunity prevent a nonimmune individual from acquiring a disease? Give an example.

Figure 30.4 Herd immunity and transmission of infection. Immunity in some individuals protects susceptible individuals from infection. (a) In a population with no immunity, transfer of a pathogen from one infected individual can ultimately infect (arrows) all individuals as newly infected individuals in turn transfer the pathogen to other individuals. (b) In a population that is only moderately dense and that has some immunity against a moderately transmissible pathogen such as influenza, an infected individual cannot transfer the pathogen to all susceptible individuals because resistant individuals, immune due to previous exposure or immunization, break the cycle of pathogen transmission: Susceptible individual A becomes infected, but susceptible individuals B and C are protected. The proportion of a population that must be immune for herd immunity to be effective also varies with the disease; highly infectious diseases require a higher proportion of immune individuals for herd immunity to prevent transmission (see Table 30.3).

30.3 Infectious Disease Transmission and Reservoirs

Epidemiologists follow the transmission of a disease by correlating geographic, climatic, socioeconomic, and demographic data with disease incidence. These correlations are then used to identify possible modes of transmission and disease patterns. Epidemiologists group infectious diseases by their *mode of transmission*. This approach reflects the ecology of the organism and is the pattern we will use in Chapters 31–34.

Modes of Disease Transmission

Three major modes of infectious disease transmission are known and are summarized in Table 30.2. These include diseases transmitted from *person to person*, including those transmitted by touching *fomites* (inanimate objects); diseases transmitted by substances taken into the body (for example, food, water, or air), called *vehicles*; and diseases transmitted by *vectors*, that is, other organisms, especially those that access the bloodstream, such as ticks and biting insects. Each mechanism has three stages in common: (1) escape from the host or reservoir, (2) travel, and (3) entry into a new host.

Person-to-person disease transmission occurs when an infected host transmits a disease directly to a susceptible host without the assistance of an intermediate host. Upper respiratory infections such as the common cold and influenza are most often transmitted person to person by airborne droplets resulting from sneezing or coughing. Many of these droplets, however, do not remain airborne for long, and so transmission requires close, although not necessarily intimate, person-to-person contact. Some pathogens are extremely sensitive to environmental factors such as drying and heat and are unable to survive for significant periods of time away from the host. These pathogens, transmitted only by intimate person-to-person contact, such as exchange of body fluids in sexual intercourse, include those responsible for sexually transmitted diseases including syphilis (*Treponema pallidum*), gonorrhea (*Neisseria gonorrhoeae*), and HIV/AIDS (HIV, human immunodeficiency virus; AIDS, acquired immunodeficiency syndrome). Direct person-to-person contact is also how pathogens such as staphylococci (boils and pimples) and fungi (ringworm) are transmitted. Some of these pathogens (*Staphylococcus aureus* is a good example) can spread by vehicle transmission as well because when inoculated into a vehicle such as food, they grow rapidly and produce poisonous toxins.

In addition to direct contact between hosts, infectious diseases may also be transmitted by contact with inanimate objects or by other organisms. When contaminated with a viable pathogen, inanimate agents, called **fomites**, can transfer the pathogen to a susceptible host. A huge variety of fomites can harbor pathogens and may include bedding, clothing, toys, books, door knobs, eating utensils, paper and coin currency, and surgical instruments—virtually any object or surface that is accessible to public contact. The term **vehicle** is used to describe nonliving sources of pathogens that may transmit disease to large numbers of individuals upon entering their bodies. Common disease vehicles include contaminated food and water (Table 30.2), but air and soil may also function as vehicles of disease transmission, such as in the transmission of infectious microbial spores. A key distinction in this terminology is that fomites are nonliving objects that are *touched or handled*, whereas vehicle-associated epidemics are typically traced to a *common contaminated source*—shared commodities consumed in large amounts by local or regional populations.

Living disease carriers are called **vectors**, and arthropods (mites, ticks, fleas, etc.) and vertebrates (usually dogs, cats, or rodents) are common disease vectors. Vectors are often not definitive hosts for the pathogen but simply carry the pathogen from one host to another. For instance, many arthropods obtain their nourishment by biting and sucking blood, and if the pathogen is present in the blood, the arthropod will ingest the pathogen and transmit it when biting another individual. In some cases, viral pathogens multiply in the arthropod vector, which is then considered an *alternate host*. Such is the case for West Nile virus (in the *Culex* mosquito) and the bacterium *Yersinia pestis* (in the rat flea), the causative agent of plague (► Sections 32.6 and 32.7, respectively). Such replication leads to greater pathogen abundance in the vector, and this increases the probability that a subsequent bite will lead to infection.

A marked seasonality or periodicity of a disease often signals a particular mode of transmission. Seasonal patterns of transmission can result from environmental factors, such as weather patterns, that influence the survival of the pathogen or its vector. For example, California encephalitis—a viral disease transmitted by mosquitoes—shows a pattern in which the disease peaks during the summer and fall months but disappears in the winter, coinciding with the activity of its mosquito vector (Figure 30.5). By contrast, human influenza occurs in an annual cyclic pattern unrelated to arthropod activities, causing person-to-person epidemics propagated among schoolchildren and other populations of susceptible individuals. Cases of influenza are often high in schools or crowded offices because the virus is transmitted through the respiratory route by airborne droplets; peak incidence occurs in midwinter and early spring when schools are in session and people are indoors much of the day.

Disease Carriers and Disease Reservoirs and Control

As described earlier, a disease *carrier* is a pathogen-infected individual who has a subclinical infection and shows either no symptoms or only mild symptoms of the disease; carriers are thus potential sources of infection for others. Carriers may be in the incubation period of the disease, in which case the carrier state precedes the development of actual symptoms (Section 30.1). Respiratory infections such as colds and influenza, for example, are often spread via carriers who are unaware of their infection and so are not taking

TABLE 30.2 Major means of human infectious disease transmission	
Mode of transmission	Examples
Person to person	
Direct contact: Sexual intercourse; handshakes	Gonorrhea; <i>Staphylococcus aureus</i> infection
Indirect contact: Water glasses and other fomites	Influenza; common cold
Airborne droplets: Sneezes, coughing	Influenza; measles; tuberculosis
Vehicle	
Waterborne: Sewage-contaminated water	Cholera; giardiasis
Foodborne: Contaminated foods	Staphylococcal food poisoning; salmonellosis
Airborne: Fungal spores	Histoplasmosis; coccidioidomycosis
Soilborne: Puncture wound contaminated with soil	Tetanus
Soil aerosol or infected animal	Anthrax
Vector	
Arthropods/insects: Mites, ticks, mosquitoes	Typhus; Lyme disease; malaria

Figure 30.5 Cyclical nature of California encephalitis in the United States. California encephalitis is transmitted by the mosquito *Ochlerotatus triseriatus* (left photo) and is caused by the La Crosse encephalitis virus, a negative-strand and enveloped RNA virus (right photo). Because it depends on a seasonally available vector, disease incidence shows a sharp rise in late summer, followed by a complete decline in winter. Data are from the CDC, Atlanta, Georgia, USA.

any precautions against infecting others. The carrier state lasts only a short time for carriers who develop acute disease. However, *chronic carriers* usually appear healthy and may spread disease for extended periods of time. Some examples here include carriers of hepatitis B, typhoid fever, HIV/AIDS, tuberculosis, and upper respiratory *Staphylococcus aureus* infections.

Disease reservoirs are sites at which infectious agents remain viable and from which susceptible individuals may become infected. Reservoirs may be either animate or inanimate. Some pathogens whose reservoirs are not in animals only incidentally infect humans and cause disease. For example, some species of *Clostridium*, common soil bacteria, occasionally infect humans, causing life-threatening diseases such as tetanus, botulism, and gangrene. In these cases, the pathogen is not dependent on the host for survival, so host–pathogen balance is not required. For many pathogens (including many human pathogens), however, living organisms are the only reservoirs. In these cases, the host is essential for the life cycle of the infectious agent; maintenance of human pathogens of this kind requires host-to-host transmission. Many viral and bacterial respiratory pathogens and sexually transmitted pathogens fall into this category. When humans are the main or only disease reservoir, implementing infection controls may or may not be easy and depends to a great extent on the nature of the disease and its mode of transmission. With diphtheria, for example, confirmed cases are isolated and quarantined to prevent spread of the pathogen (Section 30.5). However, for a disease like gonorrhea, where symptoms are often inapparent in females, tracking down and treating disease carriers can be difficult if not impossible.

Some infectious diseases are caused by pathogens that reproduce in both humans and animals. A disease that primarily infects animals and is only occasionally transmitted to humans is called a **zoonosis**; rabies is a good example. The reservoir for rabies is wild mammals, primarily skunks, raccoons, foxes, and certain bats. Although person-to-person transmission of zoonoses is rare, control of zoonoses in humans is nearly impossible because of the frequent contact some humans have with wild animals and the fact that the animal reservoir can probably never be effectively controlled. Certain other infectious diseases are caused by organisms such as protists and helminths (parasitic worms) that undergo complex life cycles requiring an obligate transfer from a nonhuman host to a human host and back to the nonhuman host; the diseases malaria and schistosomiasis (Chapter 34) are good examples here. In the case of malaria, the major reservoir other than humans is the mosquito *Anopheles gambiae*, and some control of the disease can be achieved by chemical or physical controls on the insect reservoir. In schistosomiasis, by contrast, the reservoir is an aquatic snail, and so eliminating the reservoir is impossible, although treatments for the disease are possible. Interestingly, “reverse zoonoses” (transmission from humans to animals) are also possible, and for an example, see MicrobiologyNow in Chapter 33.

Check Your Understanding

- What is a zoonotic disease? A disease reservoir?
- What is the difference between a disease vehicle and a disease vector?
- An effective vaccine is available for human rabies, yet cases continue to occur every year around the world. What aspect of rabies makes it such a challenge to completely eradicate?

30.4 Characteristics of Disease Epidemics

Endemic infectious diseases are constantly present over long periods of time but typically occur at only low incidence in the population. In tropical Africa, for example, malaria is endemic; both morbidity and mortality from malaria have remained relatively constant on a long-term basis. By contrast, the 2014 outbreak of Ebola hemorrhagic fever in West Africa ran to epidemic proportions in major districts of Sierra Leone, Liberia, and Guinea. The 2019 Ebola outbreak in the Democratic Republic of Congo (along with a few cases in Uganda) infected over 3150 people, two-thirds of whom died. The prompt implementation of strict public health measures (Section 30.5) is required to contain outbreaks and limit the spread of Ebola. As a highly transmissible disease (► Section 31.12), Ebola has the potential to become pandemic if those infected but not yet showing symptoms travel away from the epidemic area. However, a highly effective Ebola vaccine, now available, may temper this prediction.

Epidemics

Disease epidemics show characteristic features and require that rapid epidemiological conclusions be reached and clinical treatment instituted if the epidemic is to be contained. The characteristic features of epidemics include distinct patterns in the disease cycle and inherent properties of the pathogen that affect its virulence and herd immunity. Major epidemics are usually classified as either *common-source epidemics* or *host-to-host epidemics*. The patterns of disease

Figure 30.6 Types of epidemics. The shape of the curve that plots incidence of an epidemic disease against time identifies the likely type of the epidemic. For a common-source epidemic, such as cholera resulting from contaminated water shared by many people, the curve rises sharply to a peak and then declines rapidly. Host-to-host infectious disease incidence rises relatively slowly as new cases accumulate. Inset photos: left, scanning electron micrograph of a *Vibrio* sp. closely related to *Vibrio cholerae*, the cholera agent; right, transmission electron micrograph of virions of H1N1 influenza virus.

incidence observed in these two types of epidemics are contrasted in **Figure 30.6**.

A **common-source epidemic** results from an infection (or intoxication) of a large number of people from a contaminated source, such as food or water, that all infected individuals have ingested. Such epidemics are often caused by a breakdown in the sanitation of a central food or water distribution system, but they can also be more local, such as contaminated food in a particular restaurant. Foodborne and waterborne common-source epidemics are primarily intestinal diseases; the pathogen leaves the body in fecal material, contaminates food or water supplies as a result of improper sanitation, and then enters the intestinal tract of the recipient during ingestion of the food or water (Chapter 33).

Common-source disease outbreaks are characterized by a rapid rise to a peak incidence because a large number of individuals become ill within a relatively brief period of time (Figure 30.6). Moreover, assuming that epidemiological surveillance quickly identifies the disease vehicle, cases of a common-source disease decline fairly rapidly, as well. Cholera is the classic example of a common-source epidemic as the disease is almost exclusively waterborne; if a sanitation breakdown occurs (or if sanitation is lacking, as is often the case in developing countries), the cholera bacterium can be shed from a carrier or an active infection into a water source used by many other people and quickly trigger an epidemic (Figure 30.6).

In contrast to the common-source disease pattern, in a **host-to-host epidemic** the disease incidence shows a relatively slow,

progressive rise (Figure 30.6) and a gradual decline. Cases continue to be reported over a period of time equivalent to several incubation periods of the disease. A host-to-host epidemic can be initiated by the introduction of a single infected individual into a susceptible population, with this individual infecting one or more people depending on the extent of herd immunity (Figure 30.4) in that population. In a host-to-host epidemic, the pathogen replicates in susceptible individuals, reaches a communicable stage, is transferred to other susceptible individuals, and again replicates and becomes communicable; such epidemics are often controlled by effective herd immunity due to previous infection or vaccination. Influenza and chicken pox (Chapter 31) are examples of diseases that can spread in host-to-host epidemics.

Basic Reproduction Number (R_0)

The infectivity of a pathogen can be predicted using mathematical models that estimate the **basic reproduction number** (R_0) that the pathogen may trigger. The R_0 is defined as the number of expected secondary transmissions from each single case of a disease in an entirely susceptible population, and **Table 30.3** lists the R_0 of selected infectious diseases. R_0 directly correlates with the herd immunity necessary to prevent spread of infection; the higher the R_0 value, the greater the herd immunity required to stop infection (Table 30.3). Unfortunately, conditions are not always ideal and the mathematical models that predict R_0 may not take into account such factors as numbers of recovered individuals, population density (close contact), length of contact time, populations of high-risk individuals, ease of travel, and other variables that may affect disease spread. As a result, R_0 is a theoretical construct and can only estimate infectivity. Nevertheless, R_0 is still a useful gauge of the relative infectivity of a pathogen and helps to establish targets for immunization coverage to prevent spread of a particular infectious disease.

We move on now to consider public health on a global basis. In the era of “globalization,” disease transmission must be considered in a global context if public health personnel are to keep epidemics from becoming pandemics.

TABLE 30.3 Basic reproduction number (R_0) and herd immunity necessary for community protection from selected infectious diseases

Disease	^a R_0	Herd immunity ^a
Diphtheria	7	85%
Influenza ^b	1.6	29%
Measles	18	94%
Mumps	7	86%
Pertussis	17	94%
Polio	7	86%
Rubella	7	85%
Smallpox	7	85%

^a R_0 and herd immunity values are the highest estimates for each disease.

^bValues shown are for the pandemic (H1N1) 2009 influenza. Each influenza epidemic has a different R_0 and herd immunity value. Herd immunity values assume a 100% effective vaccine. Vaccine efficacy for influenza is about 60% and observed herd immunity values are 40% or greater depending on the susceptible host populations.

Check Your Understanding

- Distinguish between common-source and host-to-host epidemics. Cite at least one example of each. Describe how common-source epidemics can be recognized using epidemiological surveillance data.
- Define the basic reproduction number for a pathogen. How does this value correlate to immunization requirements for herd immunity?

II • Public and Global Health

Establishing and maintaining protocols to control the vehicles and reservoirs of infectious disease is a universal goal of public health programs around the world. International cooperation is key to effectively controlling both localized outbreaks and proliferation of infectious disease.

In Part II, we focus on public health issues including some of the methods and tools used to identify, track, contain, and eradicate infectious diseases within populations. We also draw a stark contrast between the causes of mortality in developed versus developing countries. Although noninfectious diseases are the major killer in developed countries, infectious disease remains the leading cause of mortality in other countries.

30.5 Public Health and Infectious Disease

Public health refers to the health of the general population and to the activities of public health authorities in the control of disease. The incidence and prevalence of many infectious diseases dropped dramatically during the twentieth century, especially in developed countries, because of universal improvements in public health due to advances in basic living conditions. Access to safe water and food, improved public sewage treatment, less crowded living conditions, and lighter workloads have all contributed immeasurably to disease control. Several historically important diseases, including smallpox, typhoid fever, diphtheria, brucellosis, and poliomyelitis, have been controlled (and in the case of smallpox, even eliminated) by active, disease-specific public health measures, and we review these here.

Controls Directed Against Common Vehicles and Major Reservoirs

Common vehicles for pathogen dispersal include food, water, and air. The control of foodborne and waterborne pathogens (Chapter 33) has seen the greatest successes through improved methods of preventing microbial contamination of food and water. For example, water purification procedures in the United States, first instituted early in the twentieth century, dramatically reduced the incidence of typhoid fever (Figure 30.7), and laws controlling food purity, preparation, and storage, coupled with strict monitoring of the food and water distribution network, have greatly decreased the incidence of common-source diseases. However, in contrast to food and water, controlling transmission of respiratory (airborne) pathogens is much more difficult. Other than wearing personal protection such as face masks and avoiding individuals you know are infected, few effective measures of airborne infection control are possible except

Figure 30.7 Historical progression of typhoid fever in Philadelphia. The introduction of filtration and chlorination eliminated typhoid fever in Philadelphia and other cities with well-regulated water supplies. The risk of typhoid in the United States today is very low but occasional cases are reported.

in specialized environments such as hospital operating rooms where chemical and physical agents can treat the rather small amount of circulating air.

When the disease reservoir is primarily *domestic* animals, infection of humans can be prevented if the disease is eliminated from the infected animal population by vaccinating herds and removing diseased individuals. However, as we have seen (Section 30.3), when the disease reservoir is a *wild* animal, eradication is much more difficult. Eradication of rabies, for example, would require the immunization or destruction of all wild animal reservoirs, an impossible task. When insect vectors are involved, effective control can often be accomplished with insecticides. However, the use of chemicals must be balanced with health and environmental concerns because in some cases, the elimination of one public health problem (the disease vector) simply creates another (toxic chemical exposure).

When humans are the disease reservoir—as, for example, in HIV/AIDS—control and eradication can be difficult, especially, as mentioned previously in reference to gonorrhea, if there are asymptomatic carriers. By contrast, certain diseases that are limited to humans and have no asymptomatic phase can be prevented through immunization or treatment with antimicrobial or other drugs. However, the disease can be eradicated only if those who have contracted the disease and all possible contacts are immunized, treated, or if necessary, quarantined. Such a strategy was successfully employed by the World Health Organization to eradicate smallpox worldwide (see later) and is currently being used to eradicate polio.

Immunization

Smallpox, diphtheria, tetanus, pertussis (whooping cough), measles, mumps, rubella, and poliomyelitis have been controlled primarily by immunization. Diphtheria, for example, is no longer considered even endemic in the United States. Vaccines are routinely administered in childhood for a number of other infectious diseases (◀ Figure 28.8). As we emphasized in Section 30.4, 100% immunization is not necessary for effective disease control in a population because of herd immunity, although the percentage needed to

Figure 30.8 Measles immunization in the United States. The introduction of a measles vaccine eliminated measles as a common childhood infection within 20 years. Inset photos: left, transmission electron micrograph of a measles virion (a negative-strand enveloped RNA virus); right, photo of an infant showing the spotted rash characteristic of measles. With an extremely high R_0 (Table 30.3), measles outbreaks can spike quickly in unvaccinated populations.

ensure disease control is still quite high and varies with the infectivity and virulence of the pathogen (Table 30.3).

Measles epidemics offer an example of the power of herd immunity. The occasional resurgence of the highly contagious measles virus ($R_0 = 18$, Table 30.3) emphasizes the importance of maintaining appropriate immunization levels for a given pathogen. Until 1963, the year an effective measles vaccine was licensed, nearly every child in the United States acquired measles through natural infections, resulting in over 300,000 annual cases. However, after introduction of the vaccine, the number of annual measles infections decreased rapidly (Figure 30.8). Case numbers reached a low of 1497 by 1983. However, by 1990, the percentage of children immunized against measles fell to 70%, and the number of new cases rose to 27,786. A concerted effort to increase measles immunization levels to above 90% (about that needed for effective herd immunity, Table 30.3) virtually eliminated measles in the United States by the early 2000s. However, in the past several years measles incidence is once again rising due to immunization levels insufficient to maintain effective herd immunity.

Isolation, Quarantine, and Surveillance

Isolation and quarantine are effective public health measures. **Isolation** is the separation of persons who have an infectious disease from those who are healthy. **Quarantine** is the separation and restriction of well persons who may have been exposed to an infectious disease to see if they develop the disease. The length of isolation or quarantine for a given disease varies and is typically the longest

period of communicability for that disease. To be effective, these measures must prevent infected or potentially infected individuals from contacting uninfected susceptible individuals. By international agreement, six infectious diseases require isolation and quarantine: *smallpox*, *cholera*, *plague*, *yellow fever*, *typhoid fever*, and *relapsing fever*. Each is a very serious, particularly communicable disease. Spread of certain other highly contagious diseases, such as Ebola hemorrhagic fever, SARS, H5N1 influenza, and meningitis, may also be subject to quarantine or isolation as outbreaks emerge in particular regions.

As mentioned earlier (Section 30.1), disease surveillance is a major job of the epidemiologist. Table 30.4 lists the infectious diseases currently under surveillance (referred to as *reportable diseases*) in the United States. The **Centers for Disease Control and Prevention (CDC)** is the agency of the United States Public Health Service that tracks disease trends reported by physicians and other health professionals, provides the latest disease information, and forms public policy regarding disease prevention. The CDC operates a number of infectious disease surveillance programs and also carries out surveillance of major noninfectious diseases, such as

TABLE 30.4 Reportable infectious agents and diseases in the United States

Diseases caused by bacteria

Anthrax	Q fever
Botulism	Salmonellosis
Brucellosis	Shiga toxin–producing <i>Escherichia coli</i> (STEC)
Chancroid	Shigellosis
<i>Chlamydia trachomatis</i> infection	Spotted fever rickettsiosis
Cholera	Streptococcal toxic shock syndrome
Diphtheria	<i>Streptococcus pneumoniae</i> , invasive disease
Ehrlichiosis/Anaplasmosis	Syphilis, all stages
Gonorrhea	Tetanus
<i>Haemophilus influenzae</i> , invasive disease	Toxic shock syndrome (staphylococcal)
Hansen's disease (leprosy)	Tuberculosis
Hemolytic uremic syndrome	Tularemia
Legionellosis	Typhoid fever
Listeriosis	Vancomycin-intermediate <i>Staphylococcus aureus</i> (VISA)
Lyme disease	Vancomycin-resistant <i>Staphylococcus aureus</i> (VRSA)
Meningococcal disease (<i>Neisseria meningitidis</i>)	Vibriosis (non-cholera <i>Vibrio</i> infections)
Pertussis	
Plague	
Psittacosis	

Diseases caused by viruses

Arboviruses (encephalitis, non-neuroinvasive disease, and Zika)	Rabies
Dengue	Rubella
Hantavirus pulmonary syndrome	Severe acute respiratory syndrome (SARS-CoV)
Hepatitis A, B, C	Smallpox
HIV infection/AIDS	Varicella (chicken pox)
Novel influenza A	Viral hemorrhagic fevers
Measles	West Nile virus
Mumps	Yellow fever
Polio	

Diseases caused by protists

Babesiosis
Cryptosporidiosis
Cyclosporiasis
Malaria
Giardiasis

Disease caused by a helminth

Trichinellosis (trichinosis)

Disease caused by a fungus

Coccidioidomycosis/Valley fever

cancers, heart disease, and stroke. The overall practical goal of disease surveillance is to formulate and implement plans for diagnosis and treatment of infections.

Pathogen Eradication

Concerted disease eradication programs can sometimes completely eradicate an infectious disease, and such was the case with naturally occurring smallpox, eradicated worldwide in 1980. Smallpox was a viral disease with a virus reservoir consisting solely of the individuals with acute smallpox infections, and transmission was exclusively person-to-person through direct contact. Although smallpox cannot be treated once acquired, immunization practices have been very effective. The World Health Organization (WHO) implemented a smallpox eradication plan in 1967. Because of the success of previous vaccination programs, smallpox had already been confined to endemic status in parts of Africa, the Middle East, and the Indian subcontinent. WHO field health workers proceeded to vaccinate everyone in these areas they could locate with the goal of providing either direct or herd immunity (Section 30.2) to the entire population. Each subsequent outbreak or suspected outbreak was targeted by WHO teams that quickly traveled to the outbreak site, isolated individuals with active disease, and vaccinated all contacts. To break the chain of possible infection, they then immunized everyone who had contact with the contacts, and this aggressive vaccination policy eventually eliminated smallpox.

Several other communicable diseases are candidates for global eradication. Poliomyelitis, like smallpox a viral disease with a human-only reservoir, is on its way to elimination using the same vaccination strategy used against smallpox; in 2018, a total of only 33 cases of wild polio were reported worldwide. Diseases caused by parasites have also been targeted, including Chagas disease (by treating active cases and destroying the insect vector) and dracunculiasis (by treating drinking water to prevent transmission of *Dracunculus medinensis*, the Guinea helminth parasite). Eradication of certain bacterial diseases is also on the horizon. For example, syphilis is a candidate because the disease is found only in humans and is readily treatable with antibiotics. Diphtheria, caused by the bacterium *Corynebacterium diphtheriae*, could also be eradicated worldwide by application of the strict immunization protocols that have virtually eliminated diphtheria from North America.

- Outline the steps taken to eradicate smallpox.
- Describe some of the public health activities of the U.S. Centers for Disease Control and Prevention.

30.6 Global Health Comparisons

The World Health Organization (WHO) has divided the world into six geographic regions for the purpose of collecting and reporting health information, such as causes of morbidity and mortality. These geographic regions are Africa, the Americas (North America, the Caribbean, Central America, and South America), the eastern Mediterranean, Europe, Southeast Asia, and the western Pacific. Here we compare mortality data from a relatively developed region,

the Americas, to those from a developing region, Africa, to emphasize the fact that infectious diseases are still major causes of morbidity and mortality in many regions of the world.

Infectious Disease in the Americas and Africa

Mortality statistics in developed and developing countries are significantly different, as illustrated by a comparison of data from the Americas and from Africa in 2016 when the worldwide population was nearly 7.5 billion. Worldwide, 56.9 million individuals died, giving a mortality rate of 7.6 deaths per 1000 inhabitants per year, and 11.4 million (20%) of these deaths were attributable to infectious diseases. There were 992 million people in the Americas in 2016, and there were 6.9 million deaths, or 6.9 deaths per 1000 persons per year. In Africa, there were 1.02 billion people in 2016 and 8.8 million deaths, or 8.7 deaths per 1000 persons per year. These statistics show differences in overall mortality between developed and developing regions, but a comparative examination of the causes of mortality is even more instructive.

Figure 30.9 indicates that infectious diseases caused the most deaths in Africa, whereas in the Americas, noninfectious diseases,

Figure 30.9 Causes of death in Africa and the Americas, 2016. Noninfectious diseases include cancer, cardiovascular diseases, and diabetes. Injuries include accidents, murder, suicide, and war. Data are from the World Health Organization, Geneva.

such as cancer and cardiovascular disease, were the leading causes of mortality. In Africa, there were about 4.9 million deaths due to infectious diseases, and the life expectancy was 61 years of age. The African death toll due to infectious diseases was nearly 9% of the total deaths in the world. In stark contrast, only 679,546 died of infectious disease in the Americas, and the life expectancy was 75 years of age.

The higher life expectancy in developed countries is a direct consequence of the reduction in death rates from infection over the last century, and most of these gains are due to advances in public health. By contrast, lack of resources in developing countries limits access to adequate sanitation, safe food and water, immunizations, healthcare, and medicines, leading to increases in infectious diseases and, as a consequence, to significantly shorter life expectancy. Interestingly, some health professionals predict that life expectancies in certain developed regions may soon begin to decrease, but this is not attributed to infectious diseases. On the contrary, lifestyle diseases are emerging as a major health factor in the Americas, and obesity-related health complications, such as type 2 diabetes, coronary heart disease, and hypertension, are becoming more prevalent.

Travel to Endemic Areas

The high incidence of disease in many parts of the world is a concern for people traveling to such areas. However, travelers can be immunized against many of the diseases that are endemic in foreign countries. Specific recommendations for immunization for those traveling abroad are updated biannually and published by the CDC (<http://www.cdc.gov/>).

For many countries, immunization certificates for yellow fever are required for entry from areas with endemic yellow fever. These areas include much of equatorial South America and Africa. Most other nonstandard immunizations, such as those for rabies and plague, are recommended only for people who are expected to be at high risk, such as veterinary healthcare providers. The CDC summarizes current information for the potential for infectious disease transmission throughout the world, including diseases for which currently there are no effective (or only experimental) vaccines (for example, HIV/AIDS, malaria, Ebola hemorrhagic fever, dengue fever, amebiasis, encephalitis, and typhus). Travelers should take precautions, such as avoiding insect and animal bites, drinking only water that has been properly treated to kill all microorganisms, eating properly stored and prepared food (and avoiding fresh uncooked foods), and undergoing antibiotic and chemotherapeutic programs for prophylaxis or for suspected exposures. Although these precautions do not guarantee that one will remain disease-free, adhering to them greatly reduces the risk of infection.

Sometimes diseases appear to “come out of nowhere” or, alternatively, reappear after a long absence. In the final part of this chapter, we explore these interesting cases of infectious disease.

Check Your Understanding

- Contrast mortality due to infectious diseases in Africa and the Americas.
- Do you know what vaccinations you have received? List infectious diseases for which you have not been immunized and with which you could come into contact next year.

III • Emerging Infectious Diseases, Pandemics, and Other Threats

Emerging diseases, infectious disease pandemics, and the malicious use of bioweapons present a constant threat to human welfare. Vigilant surveillance is necessary to detect these threats to global health and to respond in an effective way.

In recent years, new infectious diseases have emerged and established diseases have reemerged with alarming frequency. In Part III of this chapter, we discuss some of these diseases and the reasons for their sudden emergence or reemergence. We also investigate the potential for the purposeful use of infectious microbes as agents of war or civilian terror.

30.7 Emerging and Reemerging Infectious Diseases

Infectious diseases are global, dynamic health problems. In this section we examine some recent patterns of infectious disease, some reasons for the changing patterns, and the methods used by epidemiologists to identify and deal with new threats to public health.

Emerging and Reemerging Diseases

The worldwide distribution of diseases can change dramatically and rapidly. Alterations in the pathogen, the environment, or the host population contribute to the spread of new diseases, with potential for high morbidity and mortality. Diseases that suddenly become prevalent are called **emerging diseases** and are not limited to “new” diseases; they also include **reemerging diseases**, diseases that were previously under control but suddenly appear as a new epidemic. Examples of global emerging and reemerging disease are shown in [Figure 30.10](#), and select diseases with high potential for emergence or reemergence are described in [Table 30.5](#). Occasionally, new diseases emerge unexpectedly and for unknown reasons. For example, within just a few years of its discovery, the drug-resistant yeast *Candida auris* is an emerging pathogen that is becoming a significant concern as a causative agent of serious healthcare-associated infections (see MicrobiologyNow at the opening of this chapter).

Emerging epidemic diseases are not a new phenomenon. Among the diseases that rapidly and sometimes catastrophically emerged in the past are plague (caused by the bacterium *Yersinia pestis*) and influenza. For example, in the Middle Ages, up to one-third of all humans were killed by the periodic plague epidemics that swept across Europe, Asia, and Africa. Influenza caused a devastating worldwide pandemic in 1918–1919, claiming up to 100 million lives, and the pandemic H1N1 influenza virus that emerged in 2009 killed up to a half million people in its first year. In the 1980s, HIV/AIDS and Lyme disease emerged as new diseases, and health officials worldwide are paying particular attention to the potential for rapid emergence of pandemic influenza developing from H5N1 avian influenza. In 2014 and again in 2019, isolation of patients and extra protections for their caregivers were practiced during the West African and central African Ebola hemorrhagic fever epidemics ([▶ Section 31.12 and Figure 31.34b](#)) to prevent the spread of this extremely dangerous viral disease.

Figure 30.10 Recent outbreaks of emerging and reemerging infectious diseases. The diseases shown are local outbreaks capable of producing widespread epidemics and pandemics. Not shown are established pandemic diseases such as HIV/AIDS and predictable annual epidemic diseases such as seasonal epidemic human influenza. MERS, Middle East respiratory syndrome. Avian influenza is caused by influenza A H5N1 (Section 30.8).

TABLE 30.5 Emerging and reemerging epidemic infectious diseases			
Agent	Disease and symptoms	Mode of transmission	Cause of emergence
Bacteria			
<i>Borrelia burgdorferi</i>	Lyme disease: rash, fever, neurological and cardiac abnormalities, arthritis	Bite of infective <i>Ixodes</i> tick	Increase in deer and human populations in wooded areas
<i>Mycobacterium tuberculosis</i>	Tuberculosis: cough, weight loss, lung lesions	Sputum droplets (exhaled through a cough or sneeze) from a person with active disease	Antimicrobial drug resistance as multidrug-resistant and extensively drug-resistant tuberculosis
<i>Clostridioides difficile</i>	Antibiotic-associated enterocolitis	Person-to-person contact and through fomites in the healthcare setting	Gut dysbiosis due to long-term use of antibiotics
<i>Vibrio cholerae</i>	Cholera: severe diarrhea, rapid dehydration	Water contaminated with the feces of infected persons; food exposed to contaminated water	Poor sanitation and hygiene; carried to non-endemic areas via infected travelers and commerce
Viruses			
Dengue	Hemorrhagic fever	Bite of an infected mosquito (primarily <i>Aedes aegypti</i>)	Poor mosquito control; increased urbanization in tropics; increased travel and shipping
Filoviruses (Marburg, Ebola)	Fulminant, high mortality, hemorrhagic fevers	Direct contact with infected blood, organs, secretions, and semen	Contact with vertebrate reservoirs
Influenza H5N1 (avian influenza)	Fever, headache, cough, pneumonia, high mortality	Direct contact with infected animals or humans, not easily spread via respiratory aerosols	Danger of animal–human virus reassortment; antigenic shift
Zika	Asymptomatic, or fever, rash, muscle and joint pain, headache	Bite of an infected mosquito (primarily <i>Aedes aegypti</i>), mother to fetus, sexual contact, blood transfusion	Poor mosquito control; increased urbanization in tropics
Fungi			
<i>Candida</i>	Candidiasis: fungal infections of the gastrointestinal tract, vagina, and oral cavity	Member of endogenous microbiota becomes an opportunistic pathogen; contact with secretions or excretions from infected persons	Immunosuppression; medical devices (catheters); antibiotic use

Emergence Factors

Many factors play into the emergence of new pathogens, including human demographics and behavior, economic development, global travel, public health breakdowns, and other factors. The movement of humans from rural to urban areas facilitates disease transmission. For example, high population densities in cities have facilitated transmission of dengue fever (► Section 32.5), a serious mosquito-borne viral disease that infects about 400,000 people yearly, mostly in tropical and subtropical urban areas, including far southern reaches of the United States (Figure 30.11). Human behavior in large population centers, such as sexually promiscuous practices that cause the spread of hepatitis and HIV/AIDS, also contributes to disease emergence. Changes in land use may also promote the spread of disease. For example, Lyme disease, the most common vectorborne disease in the United States, is on the rise largely due to residential reforestation efforts, which increase contact between Lyme-infected deer ticks and humans, consequently increasing disease incidence.

Common-source foodborne disease epidemics occur when sanitation measures in the food industry fail. In 2009, a single U.S. meat-processing plant spread *Escherichia coli* O157:H7 to people in eight states. The contaminated food source, ground beef, was recalled and the epidemic was eventually stopped, but not before several people died. International travel and commerce also affect the spread of pathogens. For example, a single person harboring Ebola virus on an international flight could infect many other passengers because of the ease with which the Ebola virus spreads (► Section 31.12). In such cases, the disease can rapidly spread to major population centers if healthy passengers who had contact with the diseased passenger become infected and then disembark and continue their travels.

Pathogen adaptation can contribute to disease emergence. For example, most RNA viruses, including influenza and HIV, mutate rapidly. These mutant RNA viruses present major epidemiological problems because their altered genomes often affect their antigens, making immunity to old viral antigens ineffective for neutralizing the mutant viruses. Bacterial genetic mechanisms are also capable of enhancing virulence and promoting emergence of new

epidemics. Virulence-enhancing factors are often carried by mobile genetic elements (Chapter 13) that can be transferred between members of the same species, and sometimes to other species, as well. Such transfers can quickly generate emerging pathogens, and multidrug-resistant strains of *Staphylococcus aureus* and *Pseudomonas aeruginosa* are good examples of this.

A breakdown of public health measures is sometimes responsible for the emergence or reemergence of diseases. For instance, cholera (caused by *Vibrio cholerae*) can be adequately controlled, even in endemic areas, by providing proper sewage disposal and water sanitation. As discussed in Section 30.8, any compromise to water treatment systems, especially as a result of natural disasters such as earthquakes and flooding, can cause local outbreaks. Inadequate public vaccination programs can also lead to the resurgence of previously controlled diseases. For example, pertussis, a serious but preventable childhood respiratory disease, has increased recently in Eastern Europe and in the United States, partly because of inadequate immunization among adults and children.

Finally, weather patterns can also upset the usual host–pathogen balance. Disease vectors such as mosquitoes have been moving northward in response to climate change. Even a single seasonal weather abnormality can have an effect, as evidenced by the 1993 hantavirus hemorrhagic fever outbreak in the American Southwest (► Section 32.2). A very mild winter coupled with record rainfall led to an explosive increase in the population of rodents that can host hantavirus. This increased exposures for susceptible human hosts and led to the spread of this lethal zoonotic disease.

The Emergence of Toxigenic *Clostridioides difficile*

In many cases, antibiotic use itself can be a driver of pathogen emergence. As discussed in Chapter 24, prolonged use of antibiotics to treat infections can lead to enteric *dysbiosis*, a disruption to the composition of the normal gut microbiota. Opportunistic pathogens that are resistant to these antibiotics can then flourish, causing potentially serious secondary infections. *Clostridioides* (formerly *Clostridium*) *difficile* is one of these pathogens (Figure 30.12), and it has rapidly emerged over the past two decades as a major cause of life-threatening, antibiotic-associated enterocolitis (inflammation of the digestive tract).

Causing nearly half a million cases of illness and about 30,000 deaths every year in the United States alone, mostly among the elderly and immunocompromised, *C. difficile* has become a considerable medical challenge. About 80% of cases of *C. difficile* infection (CDI) are healthcare-associated (nosocomial, ◀ Section 29.2) and occur in those age 65 and older. In addition to being multidrug resistant, *C. difficile* is able to form endospores (Figure 30.12b; ◀ Section 2.8). These highly resistant structures can remain viable following standard disinfection and hygiene protocols used in the healthcare setting, including resistance to alcohol-based hand sanitizers, and therefore the bacterium tends to persist on fomites and surfaces. Subsequent transfer of the endospores, often through healthcare personnel that have come into contact with contaminated materials, to patients undergoing long-term antibiotic treatment can lead to the onset of life-threatening diarrheal colitis.

Figure 30.11 Dengue virus 2018. Dengue virus is now found in all tropical and subtropical countries as a result of the spread of its *Aedes aegypti* mosquito vector. The red areas are now endemic for the virus and mosquito vector. The red dots indicate outbreaks outside the known endemic areas. Prior to 1981, dengue virus was unknown in the Americas. Data are from the CDC, Atlanta, Georgia, USA.

Figure 30.12 *Clostridioides difficile*, an emerging pathogen and causative agent of antibiotic-associated enterocolitis. (a) Plate culture of *C. difficile* grown on cycloserine-cefoxitin-fructose agar. The culture is illuminated with ultraviolet light, resulting in a chartreuse fluorescence from the colonies. (b) Photomicrograph showing cells of *C. difficile*. Note the developing endospores (arrows) inside the rod-shaped cells.

The symptoms of CDI are caused by the production of two exotoxins: toxin A (TcdA) and toxin B (TcdB). These toxins are glucosyltransferases that inactivate guanosine triphosphatases in colonic epithelial cells. This activity disrupts actin dynamics in the cytoskeleton and eventually kills the cells. Antibiotic treatment of CDI using metronidazole, vancomycin, or the more recently approved fidaxomicin, a bactericidal antibiotic that inhibits RNA synthesis, is not universally effective. There is evidence that implementing a high-fiber diet can aid in recovery from CDI, but by far the most effective treatment to date has been *fecal transplant*, the infusion of fecal matter and its associated gut microbiota from a healthy donor into the diseased patient (◀ Section 24.11). This treatment has shown remarkable success in allowing full recovery from *C. difficile* infection in up to 95% of cases.

Addressing Emerging Diseases

The keys for addressing emerging diseases are prompt recognition of the disease and intervention to prevent pathogen transmission. Emerging diseases have, at least at first, low incidence and are usually absent from the official notifiable disease list for the United States prepared by the CDC (Table 30.4). Emerging diseases are first recognized from their unique epidemic incidence, clusters and other epidemiological patterns, and clinical symptoms unrelated to known pathogens. Such disease patterns trigger intensive public health surveillance followed by specific interventions designed to control further outbreaks. Methods such as isolation, quarantine, immunization, and drug treatment can be applied to contain outbreaks. For vectorborne and zoonotic diseases, the nonhuman host or vector must be identified to intervene in the life cycle of the pathogen and stop human infection.

International public health surveillance and intervention programs were instrumental in controlling the emergence of severe acute respiratory syndrome (SARS), a disease that appeared suddenly in Asia and unpredictably from a zoonotic source. On the other hand, even a rapid and focused response was unsuccessful in containing the spread of pandemic (H1N1) 2009 influenza, as we will see in the next section.

Check Your Understanding

- What is the difference between an emerging and a reemerging infectious disease?
- What factors are important in the emergence or reemergence of potential pathogens, such as *Clostridioides difficile*?
- Indicate general and specific methods that would be useful for identifying emerging infectious diseases.

30.8 Examples of Pandemics: HIV/AIDS, Cholera, and Influenza

Through the centuries, several diseases have reached pandemic proportions. Here we consider three—HIV/AIDS, cholera, and influenza—for which epidemiological studies have been extensive.

HIV/AIDS

HIV/AIDS is a continuum of disease, starting with the infection of an individual with the human immunodeficiency virus (HIV). Eventually, infection results in acquired immunodeficiency syndrome (AIDS), a disease which, if not treated, cripples the immune system, leading to opportunistic infections that can be fatal (▶ Section 31.15). The first reported cases of AIDS were diagnosed in the United States in 1981. Since then, more than 1.2 million cases have been reported in the United States with over 650,000 deaths (Figure 30.13); worldwide, about 35 million AIDS deaths have occurred.

Figure 30.13 Annual new cases of human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) in the United States. Cumulatively, there were about 1.3 million cases of HIV/AIDS through 2016. In 2009, the HIV/AIDS case definition changed to include all new HIV infections and AIDS diagnoses (▶ Section 31.15). Colored arrows indicate the introduction of different anti-HIV drugs. See Sections 28.6 and 31.15 for a discussion of anti-HIV therapies. Data are from the HIV Surveillance Report: Diagnosis of HIV Infection in the United States and Dependent Areas, 2017, CDC, Atlanta, Georgia, USA.

Figure 30.14 Distribution of AIDS cases by risk group and gender in the United States, 2016. Data from the CDC, Atlanta, Georgia, USA, were gathered from 31,931 males and 7,528 females diagnosed with HIV/AIDS in 2016.

Epidemiological studies in the United States in the 1980s suggested a high AIDS prevalence among men who have sex with men and among intravenous drug abusers. Individuals receiving blood or blood products were also at high risk. Collectively, these epidemiological data indicated a transmissible agent transferred during sexual activity or by contaminated blood. Soon after the discovery of HIV in 1983, laboratory tests were developed to detect antibodies to the virus in blood. With this tool in hand, surveys of HIV incidence and prevalence defined the spread of HIV and showed conclusively that body fluids, primarily blood and semen, were the vehicles for transmission of the virus (Figure 30.14).

The HIV/AIDS data showed that in the United States, the number of AIDS cases was disproportionately high in men who have sex with men, but among women, heterosexuals were the largest risk group (Figure 30.14). Further analyses of the epidemiological data showed that the new infection rate for African American men was seven times that of Caucasian males, indicating that social and economic factors may also influence infection risk. However, regardless of

gender or racial specifics, AIDS epidemiology provided a clear picture of HIV transmission: Virtually all who acquired HIV engaged in sex or intravenous drug use in which body fluids—semen or blood—were transferred and commonly had sex or exchanged syringe needles with multiple partners. We discuss the pathology and therapy of HIV/AIDS in Section 31.15.

Cholera

Cholera is primarily a waterborne infection (► Section 33.3 and Figure 33.2) that is normally kept in check by appropriate public health measures for water treatment (Chapter 22). Cholera is caused by ingestion of contaminated water containing *Vibrio cholerae*, a gram-negative, curved rod-shaped species of *Proteobacteria* that produces a powerful enterotoxin that triggers severe diarrhea (◄ Section 25.6 and Figure 25.16). Cholera is endemic in Africa, Southeast Asia, the Indian subcontinent, and Central and South America. Epidemic cholera occurs frequently in areas where sewage treatment either suffers a major breakdown, as can result from a flood or an earthquake, or is inadequate or altogether absent. Indeed, it is estimated that a greater percentage of the world's population has access to cellular phones than to water sanitation facilities. In 2016, the World Health Organization (WHO) reported over 130,000 cases of cholera that led to 2420 deaths. However, the WHO estimates that only 5–10% of cholera cases are actually reported because diarrheal diseases from various pathogens are so common (Table 30.1); thus, total worldwide incidence of cholera likely exceeds 1 million cases per year.

Epidemic cholera may develop into pandemics when travelers from endemic areas carry the pathogen to new locations with susceptible populations and poor sanitation. Since 1817, cholera has swept the world in seven major pandemics (Figure 30.15). All but one of these originated on the Indian subcontinent, where cholera is endemic. Two distinct pandemic strains of *V. cholerae* are recognized, known as the *classic* and the *El Tor* biotypes. The *V. cholerae* O1 *El Tor* biotype started the seventh pandemic in Indonesia in 1961, and its spread continues to the present day. This pandemic has caused over 5 million cases of cholera and at least 250,000 deaths and continues to be a major cause of morbidity and mortality, especially in developing countries (Figure 30.15).

Figure 30.15 Cholera pandemic timeline. Seven cholera pandemics have been nearly consecutive for over 200 years. The seventh pandemic started in 1961 and is ongoing. The O139 strain that appeared in 1991 is endemic to Bangladesh and the Bay of Bengal and is causing epidemics that may be the prelude to an eighth pandemic.

In October 2010 Haiti experienced its first cholera in over 100 years, and in just two years experienced nearly 600,000 cases and 8000 deaths. The outbreak began in the aftermath of the catastrophic 2010 earthquake. There were likely two triggers of this cholera outbreak, the first being a classic scenario of poor sanitation following a disaster and the second an accidental importation from an outside source. *Vibrio cholerae* is present in marine waters, and as a result of the earthquake, cells of this pathogen may have washed into coastal freshwaters where they contaminated drinking water sources. But in addition, United Nations aid workers that arrived from Nepal, where a recent cholera outbreak had occurred, inadvertently shed *V. cholerae* into sanitation streams that found their way into Haitian drinking water sources.

Pandemic (H1N1) 2009 and Future Influenza Pandemics

Human influenza pandemics occur every 10 to 40 years as a result of major genetic changes in the influenza A virus genome that affect the virus's immune status (*antigenic drift* and *antigenic shift*, ► Section 31.8 and Figure 31.26). The most devastating influenza pandemic of all time occurred in 1918; this flu infected over half a *billion* people worldwide and killed approximately 50 *million* people before it ran its course. The 1918 pandemic was caused by a strain of influenza termed H1N1.

A more recent influenza pandemic began in March 2009 with the outbreak of epidemics in Mexico. The culprit virus, a strain designated (H1N1) 2009, was a hybrid of the 1918 strain and a later strain that caused a pandemic in 1957; (H1N1) 2009 contained genes from bird, swine, and human influenza viruses. Such *reassortant viruses*, as they are called (► Section 31.8), can be highly virulent, as they tend to produce antigens to which humans have no prior exposure and thus no immunity.

Without prior exposure and with no effective vaccine at the ready, the stage was set for the reassortant (H1N1) 2009 flu to spread rapidly and reach pandemic proportions. Within six months of its emergence, (H1N1) 2009 had spread to almost every country in the world, qualifying it as a true pandemic (Figure 30.16). Although official numbers range widely, it is estimated that more than a quarter of the world's population was infected in the pandemic. In the United States, about 60 million persons were infected, with mortality confirmed as due to (H1N1) 2009 numbering about 3400 persons. By late 2010 the (H1N1) 2009 pandemic was fading, and today few cases are observed because antigens from this strain of virus are typically included in seasonal influenza vaccines (◄ Table 28.3).

Could new influenza pandemics sweep across the world? Perhaps the greatest threat to global stability would be another influenza pandemic that has the virulence and infectivity of the 1918 pandemic. Because epidemiological surveillance is currently so extensive, this possibility is unlikely, but the risk can never be zero. In recent years public health officials worldwide have been following the emergence and reemergence of a potentially devastating strain of influenza virus designated influenza A H5N1, originally found in birds. This virus first appeared in Hong Kong in 1997, jumping directly from chickens and ducks to humans. Since then H5N1 has reemerged several times in small outbreaks, with the most recent occurring in Egypt, Indonesia, Cambodia, Bangladesh, and China (Figure 30.10). Through 2018, 860 cases of human H5N1 infection have been confirmed, resulting in 454 deaths, for a mortality rate of 53%. This high mortality rate underscores the lethal potential of this virus.

Number of confirmed cases of (H1N1) 2009 influenza
 ■ > 50,000 ■ > 5,000 ■ > 500 ■ > 50 ■ < 50

Figure 30.16 Pandemic (H1N1) 2009 influenza incidence. Data show minimal estimates of cases worldwide by country. It is estimated that approximately 1.7 billion people were infected by the (H1N1) 2009 pandemic flu (24% of the total population) and that deaths were between 150,000 and 575,000 [the large range for mortality estimates is because many deaths that were likely due to (H1N1) 2009 were not confirmed as such].

Besides poultry and humans, H5N1 has also infected swine. If a reassortant strain were to emerge from pigs and had the capacity to spread from person to person, such a virus could trigger an influenza pandemic of unprecedented mortality. Because of this, plans are in place nationally and internationally to provide appropriate vaccines and support for potential pandemics initiated by this and other emergent influenza strains. We discuss the disease influenza in detail in Section 31.8.

Check Your Understanding

- Describe the major risk factors for acquiring HIV infection in the United States. How do these differ in males and females?
- Identify the most likely means of acquiring cholera. Why do cholera epidemics keep occurring?
- What is a reassortant influenza virus and why can such viruses be so dangerous?

30.9 Public Health Threats from Microbial Weapons

As if avoiding the wrath of pathogenic microbes that can infect us naturally is not enough, humans have researched the use of certain pathogens as weapons to be intentionally deployed on others. **Biological (microbial) warfare** is the use of microbial agents to incapacitate or kill a military or civilian population in an act of war or terrorism. Although the use and development of microbial weapons are forbidden by international law, microbial weapons have already seen use, and facilities for their production likely exist in rogue countries and perhaps also in avowed terrorist groups. Because of this, microbial weapons research continues in many peaceful nations so as to best understand the most serious threats and learn how to counter them.

Characteristics of Microbial Weapons

Effective microbial weapons are pathogens, or in a few cases toxins, that are (1) relatively easy to produce and deliver, (2) safe for use by the offensive forces, and (3) able to incapacitate or kill people in a systematic and consistent manner. Although microbial weapons are potentially useful in the hands of conventional military forces, the greatest likelihood of microbial weapons use is by terrorists because of the ready availability and low cost of producing and propagating many of the organisms.

Virtually all pathogenic bacteria or viruses can potentially be used for biological warfare, and *select agents* that have significant potential for use as microbial weapons are listed in Table 30.6. The most frequently mentioned candidates are smallpox virus and *Bacillus anthracis*, the bacterium that causes anthrax. Both of these microbes can be easily disseminated, are transmissible from person to person, and typically cause high mortality. Other agents have their advantages and disadvantages as microbial weapons and are categorized as to their potential risk from Category A to Category C in Table 30.6.

TABLE 30.6 Select agents and diseases by bioweapons threat category ^a
Category A
Highest-priority agents that pose a risk to national security. These agents are easily disseminated or transmitted and result in high mortality rates. They require special action for public health preparedness.
Disease/Pathogen
Anthrax (<i>Bacillus anthracis</i>) Botulism (<i>Clostridium botulinum</i> toxin) Plague (<i>Yersinia pestis</i>) Smallpox (<i>Variola major</i>) Tularemia (<i>Francisella tularensis</i>) Viral hemorrhagic fevers (filoviruses [e.g., Ebola, Marburg] and arenaviruses [e.g., Lassa, Machupo])
Category B
Second-highest-priority agents. These agents are moderately easy to disseminate, result in moderate morbidity and low mortality, and require specific enhancements of public health diagnostic capacity and disease surveillance.
Disease/Pathogen
Brucellosis (<i>Brucella</i> species) Epsilon toxin of <i>Clostridium perfringens</i> Food safety threats (e.g., <i>Salmonella</i> spp., <i>Escherichia coli</i> O157:H7, <i>Shigella</i>) Glanders (<i>Burkholderia mallei</i>) Meliodosis (<i>Burkholderia pseudomallei</i>) Psittacosis (<i>Chlamydophila psittaci</i>) Q fever (<i>Coxiella burnetii</i>) Ricin toxin from <i>Ricinus communis</i> (castor beans) Staphylococcal enterotoxin B (<i>Staphylococcus aureus</i>) Typhus fever (<i>Rickettsia prowazekii</i>) Viral encephalitis (alphaviruses such as Venezuelan equine encephalitis, eastern equine encephalitis, western equine encephalitis) Water safety threats (<i>Vibrio cholerae</i> , <i>Cryptosporidium parvum</i> , and others)
Category C
Third-highest-priority agents are emerging pathogens that are available, easily produced and disseminated, with high potential for high morbidity and mortality.
Pathogens
Emerging infectious diseases such as hantavirus

^aSource: Centers for Disease Control and Prevention, Atlanta, Georgia, USA.

The United States government, through the Centers for Disease Control and Prevention, has developed the Select Agent Program surveillance system to monitor possession and use of potential bioterrorism agents. In addition, the CDC Laboratory Response Network and the Health Alert Network have been upgraded to enhance their diagnostic capabilities and increase the reporting abilities of local and regional healthcare centers to rapidly identify bioterrorism events as well as emerging diseases.

Smallpox and Anthrax

Smallpox virus (Figure 30.17a) has intimidating potential as a microbial weapon because it can be spread easily by direct contact or by aerosol spray; is highly debilitating; causes a high fever, severe fatigue, and the eventual formation of pus-filled skin blisters (Figure 30.17b); and has a mortality rate of 30% or higher. Although an extremely effective smallpox vaccine is available, it has not been in use in the general population since smallpox was eradicated worldwide in 1980. Moreover, the potential of smallpox virus being deployed as a military weapon is considered low because military personnel are routinely vaccinated. Nevertheless, preparations for a potential smallpox attack on civilians in the United States have been made and would include immunization of key individuals, such as those attending smallpox patients or handling clinical specimens from smallpox patients.

(a)

(b)

Figure 30.17 Smallpox and its use as a microbial weapon. (a) Smallpox virus, a double-stranded DNA virus (◀ Section 11.6). (b) Characteristic papular smallpox rash and blisters on the arm. Smallpox was officially declared eradicated worldwide in 1980.

Figure 30.18 *Bacillus anthracis* and anthrax. (a) *Bacillus anthracis* is a gram-positive, endospore-forming rod approximately 1 μm in diameter and 3–4 μm in length. Note the developing endospores (arrows). (b) Characteristic “ground glass” appearance of colonies of *B. anthracis* on blood agar plates. (c) Cutaneous anthrax. The blackened lesion seen on this forearm is called an eschar, and results from tissue necrosis. (d) Inhalation anthrax can cause cerebral hemorrhage, as shown by the dark coloration in this fixed and sectioned human brain removed at autopsy.

Bacillus anthracis is the causative agent of anthrax, and its unique properties allow it to be easily employed as a bioweapon. Chief among these is that it is easily grown aerobically, producing distinctive colonies on enriched culture media, and it differentiates into highly resistant endospores (Figure 30.18a, b; ◀ Section 2.8). Once prepared, endospores can be dried and stored indefinitely and then disseminated as a weapon by aerosol or in powdered suspension. There are three clinical forms of anthrax (▶ Section 32.8). *Cutaneous*

anthrax is contracted when abraded skin is contaminated by *B. anthracis* endospores; the organism grows and kills the skin, forming a necrotic tissue lesion called an *eschar* (Figure 30.18c). The rarest form, *gastrointestinal anthrax*, is contracted from consumption of endospore-contaminated plants or meat from animals infected with anthrax. *Inhalation anthrax* (also called *pulmonary anthrax*) is the deadliest form and is contracted when *B. anthracis* endospores are inhaled. The symptoms of inhalation anthrax include pulmonary and cerebral hemorrhaging (Figure 30.18d), which makes this form of anthrax especially dangerous. All forms of anthrax have the potential to become systemic infections; however, cutaneous anthrax is easily treatable with antibiotics and is fatal in only about 20% of untreated cases. Without treatment, gastrointestinal anthrax is fatal in about half of those infected, whereas inhalation anthrax mortality approaches 100%.

Inhalation anthrax is the form of the disease that makers of microbial weapons would aim for, as has already transpired in the United States. At least 22 cases of anthrax leading to five deaths occurred in a 2001 bioterrorism attack in which *B. anthracis* endospore preparations were mailed in envelopes to certain news outlets and government officials. Of the 22 anthrax cases, 11 were inhalational and 11 cutaneous. These weaponized anthrax endospore preparations were mixed within a fine particulate material that allowed the endospores to be spread by air currents. Thus, opening an envelope containing the lethal mixture (or releasing it into a ventilation system) could contaminate surrounding areas and personnel.

Vaccination for anthrax is possible and is restricted to individuals who are considered at risk. This includes agricultural animal workers (livestock tenders and those working with animal products), laboratory personnel working with anthrax, veterinarians, and military personnel. As was discussed with smallpox, anthrax is an unlikely military weapon but could be a very effective means of terrorizing a civilian population because the vast majority of the population is unvaccinated.

We move on now from our consideration of disease tracking to exploring human infectious diseases themselves, grouped by their mode of transmission in the final four chapters.

Check Your Understanding

- What characteristics make a pathogen or its products particularly useful as a biological weapon?
- Indicate the steps you would take to identify and treat infections from smallpox virus or anthrax in a bioterror attack.

Go to **Mastering Microbiology**
for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Principles of Epidemiology

30.1 Epidemiology is the study of the occurrence, distribution, and determinants of health and disease in populations. Epidemiologists employ surveillance measures to record the incidence and prevalence of infectious diseases and track disease outbreaks that may lead to epidemics or pandemics. The morbidity and mortality of any given disease is a

function of the transmissibility of the pathogen and the severity of the disease symptoms. Disease carriers may be symptom-free, or they may have chronic infections that are never resolved.

Q How does the job of an epidemiologist differ from that of a clinical healthcare provider?

- 30.2** Effects on populations as well as individuals must be studied to understand infectious disease. The interactions of pathogens with hosts can be dynamic, affecting the long-term evolution and survival of all species involved. Herd immunity provides disease protection for susceptible hosts.

Q Explain how the infectivity of a pathogen is correlated with the epidemic spread of a disease in various populations.

- 30.3** Infectious diseases can be transmitted directly from person to person, indirectly from living vectors or inanimate objects (fomites), or from common-source vehicles such as food and water. Disease reservoirs can include soil, insects, infected people before they show symptoms, chronic carriers, and many other sources. An understanding of disease reservoirs, carriers, and pathogen life cycles is critical for controlling disease epidemics.

Q Compared with a fomite, such as a contaminated cup, why is a disease vehicle such as food a much more powerful disease transmitter?

- 30.4** Epidemics may be of host-to-host origin or originate from a common source. The basic reproduction number (R_0) of a pathogen gives a relative picture of its seriousness and an indication of how effective herd immunity must be to prevent its spread.

Q If an emerging pathogen was found to have an R_0 of 20, would herd immunity need to be higher or lower than for an emerging pathogen with an R_0 of 5?

II • Public and Global Health

- 30.5** Food and water purity regulations, vector control, immunization, quarantine, isolation, and disease surveillance are all public health measures that reduce the incidence of communicable diseases. In the case of some diseases, such as smallpox, total eradication worldwide has been possible.

Q If an outbreak of yellow fever occurred, who would be isolated and who would be quarantined?

- 30.6** Infectious diseases account for about 20% of all mortality worldwide. Most cases of infectious diseases occur in developing countries. Control of many infectious diseases can be

accomplished by public health measures that include adequate sanitation, food and water protections, and widespread vaccination programs. A high infectious disease load can significantly reduce the average life expectancy of the population in a country.

Q Contrast the leading causes of death in Africa and in the Americas.

III • Emerging Infectious Diseases, Pandemics, and Other Threats

- 30.7** Changes in host, vector, or pathogen conditions, whether natural or artificial, can encourage the explosive emergence or reemergence of infectious diseases. Global surveillance and intervention programs by organizations such as the World Health Organization and the U.S. Centers for Disease Control and Prevention are especially attuned to emerging and reemerging pathogens to prevent local epidemics from spreading.

Q How can bacterial genetic exchange fuel the emergence of new pathogens?

- 30.8** Several infectious diseases with significant mortality show pandemic characteristics. HIV/AIDS affects those who exchange bodily fluids, most often by either promiscuous unprotected sex or intravenous drug use. Cholera is primarily a waterborne infection, and control can be achieved by maintaining adequate clean water and waste sanitation measures. New pandemic influenza strains resulting from bird–swine–human influenza reassortments present the biggest infectious disease threat worldwide.

Q Why is H5N1 avian influenza considered a major threat to public health?

- 30.9** Bioterrorism from smallpox or anthrax is a threat in a world of rapid international travel and easily accessible technical information. Aerosols or disease vehicles are the most likely modes of delivery of microbial weapons. Prevention and containment measures rely on a well-prepared public health infrastructure.

Q Why are smallpox and anthrax more likely to be bioterrorism threats to civilians than to military personnel?

APPLICATION QUESTIONS

- Smallpox, a disease that was limited to humans, was eradicated, whereas plague, a zoonotic disease with a reservoir in rats and related rodents, will likely never be eradicated worldwide. Explain this statement. Devise a plan to eradicate plague in a limited area such as a town or city. Be sure to consider methods that involve the reservoir, the pathogen, and the host.
- Like smallpox, HIV/AIDS is considered to be a disease that could be eliminated worldwide because it is propagated by known means and there are no animal reservoirs. Although eliminating HIV infection is possible, why would it be much

more difficult than eliminating smallpox? What would be involved in an HIV infection eradication program?

- H5N1 avian influenza has high potential for causing a pandemic under certain circumstances. If such a highly transmissible human–avian strain were to evolve in Asia and you were a national public health official, what measures would you employ to stop the spread of the new influenza strain to other continents? If you failed to contain the new virus, where would you expect to see the first cases of such pandemic influenza, in metropolitan or rural areas?

CHAPTER GLOSSARY

Acute infection a short-term infection, usually characterized by dramatic onset

Basic reproduction number (R_0) the number of expected secondary transmissions from each single case of a disease in an entirely susceptible population

Biological (microbial) warfare the use of microbial agents to incapacitate or kill a military or civilian population in an act of war or terrorism

Carrier a subclinically infected individual who may spread a disease

Centers for Disease Control and Prevention (CDC) the agency of the United States Public Health Service that tracks disease trends, provides disease information to the public and to healthcare professionals, and forms public policy regarding disease prevention and intervention

Chronic infection a long-term infection

Common-source epidemic an infection (or intoxication) of a large number of people from a contaminated common source such as food or water

Disability-adjusted life year (DALY) a quantitative measure of disease burden defined as the cumulative number of years lost due to an illness itself, a disability due to an illness, or premature death

Disease surveillance the observation, recognition, and reporting of diseases as they occur

Emerging disease an infectious disease whose incidence recently increased or whose incidence threatens to increase in the near future

Endemic disease a disease that is constantly present, usually in low numbers, in a population

Epidemic the occurrence of a disease in unusually high numbers in a localized population

Epidemiology the study of the occurrence, distribution, and determinants of health and disease in populations

Fomite an inanimate object that when contaminated with a viable pathogen can transfer the pathogen to a host

Herd immunity the resistance of a population to a pathogen as a result of the immunity of a large portion of the population

Host-to-host epidemic an epidemic resulting from person-to-person contact, characterized by a gradual rise and fall in number of new cases

Incidence the number of new reported cases of a disease in a population in a given time period

Isolation in the context of infectious disease, the separation of persons who have an infectious disease from those who are healthy

Morbidity the incidence of disease in a population

Mortality the incidence of death in a population

Outbreak the occurrence of a large number of cases of a disease in a short period of time

Pandemic a widespread, usually worldwide epidemic

Prevalence the total number of new and existing cases of a disease reported in a population in a given time period

Public health the health of the population as a whole

Quarantine the separation and restriction of well persons who may have been exposed to an infectious disease to see if they develop the disease

Reemerging disease an infectious disease previously under control but that produces a new epidemic

Reservoir a source of infectious agents from which susceptible individuals may be infected

Vector a living agent that transfers a pathogen (differs from genetic vector, discussed in Chapter 12)

Vehicle a nonliving source of pathogens that transmits the pathogens to large numbers of individuals; common vehicles are food and water

Virulence the relative ability of a pathogen to cause disease

Zoonosis any disease that occurs primarily in animals but can be transmitted to humans

MICROBIOLOGYNOW

Reversing Antibiotic Resistance in a Recalcitrant Pathogen

Tuberculosis (TB) is a highly prevalent and life-threatening respiratory disease, causing nearly 1.5 million deaths annually. Here we highlight a new strategy for effective treatment of this devastating disease.

The causative agent of TB, *Mycobacterium tuberculosis* (yellow-green cells in photo shown being engulfed by a macrophage, red), is a slow-growing, gram-positive and acid-fast bacterium that is treated clinically by administration of a suite of drugs for many months. Chief among these is *isoniazid*, a growth factor analog that mimics nicotinamide, a vitamin required by *M. tuberculosis* to synthesize the waxlike mycolic acids found in its tough cell wall. In the presence of isoniazid, *M. tuberculosis* cannot construct its normal cell wall, making the cells more easily penetrated by antibiotics. Unfortunately, isoniazid does not always work, and this problem is becoming increasingly common.

Isoniazid resistance in *M. tuberculosis* has been linked in part to its ability to form a biofilm (a colony of microbial cells encased in a porous organic matrix and attached to a surface)

in pulmonary tissues. The biofilm growth mode both facilitates and exacerbates the *M. tuberculosis* infection. Using a systematic screening process, researchers recently found a compound called *C10* that inhibits biofilm formation by *M. tuberculosis* in laboratory cultures. Although C10 itself showed no bactericidal activity, the bacteria were readily killed when even low concentrations of isoniazid were administered simultaneously with C10, and notably, resistance to this combination never developed. Furthermore, even strains that were already resistant to isoniazid were killed by this treatment, demonstrating that resistance to isoniazid could be *reversed* when used in combination with C10.

The next step will be to investigate the efficacy of the C10/isoniazid combination in living systems. If these tests are successful, the result may bring new potency to an old weapon against TB.

Source: Flentie, K., et al. 2019. Chemical disarming of isoniazid resistance in *Mycobacterium tuberculosis*. *Proc. Natl. Acad. Sci. (USA)* 116(21): 10510. doi:10.1073/pnas.1818009116.

Several million species of microorganisms likely exist in nature, but only a few hundred are known to cause disease. In this and the next three chapters we focus on this vitally important subset of the microbial world. We investigate the biology of the pathogens as well as the diseases they cause, including disease diagnosis, treatment, and prevention.

Our infectious disease coverage is ecological, being organized around each pathogen's *mode of transmission*. Although the biology of the different causative agents will certainly be highlighted, an ecological approach to infectious disease coverage emphasizes the single most important feature that links diseases caused by different microbes. Hence, tuberculosis and influenza are caused by a bacterium and a virus, respectively, but both diseases are transmitted from person to person by the airborne route.

In this chapter we explore diseases transmitted from person to person, whether through the air, by direct contact, or through sexual contact. In Chapter 32 we focus on diseases transmitted by animal and arthropod vectors or from soil, and in Chapter 33 we cover diseases transmitted from common sources, including water and food. We end our tour of the microbial world in Chapter 34 where we examine fungal and parasitic infections.

I • Airborne Bacterial Diseases

A wide diversity of pathogenic bacteria are transmitted through airborne particles and cause diseases ranging from relatively mild and primarily upper respiratory tract infections to life-threatening upper or lower respiratory tract infections that can compromise a patient's very ability to breathe.

Worldwide, acute respiratory infections kill more than 4 million people a year, mainly in developing countries. Children and the elderly make up most of the fatalities, but in general, respiratory infections are the most common of all human diseases. Aerosols, such as those generated by a sneeze (Figure 31.1), as well as by coughing, talking, or breathing, are major vehicles for person-to-person transmission of respiratory diseases. Besides directly infecting a new host, infectious mucus from an aerosol can also contaminate objects, such as a door handle, and transmit infection well after the aerosol event. In these ways, respiratory diseases spread quickly, especially in congested areas, as airborne pathogens exploit a simple yet highly effective means of infecting new hosts.

31.1 Airborne Pathogens

Microorganisms found in air are derived from soil, water, plants, animals, people, surfaces, and other sources. Most microorganisms survive poorly in air. As a result, airborne pathogens are effectively transmitted between people only over short distances. Certain pathogens, however, survive drying well and can remain alive in dust or on fomites for long periods of time. For example, because of their thick cell walls, gram-positive bacteria (such as species of *Staphylococcus* and *Streptococcus*) are generally more resistant to drying than are gram-negative bacteria. Likewise, the waxy layer of *Mycobacterium* cell walls resists drying and promotes survival of pathogens such as *Mycobacterium tuberculosis*.

Large numbers of droplets can be expelled during a sneeze (Figure 31.1). Infectious droplets are about 10 μm in diameter and

Figure 31.1 High-speed photograph of an unstifled sneeze. Effluent is expelled at over 100 m/s (200 miles/h).

each droplet can contain one or more microbial cells or virus virions. The initial speed of the droplet movement is about 100 m/s (200 miles/h) in a violent sneeze and ranges from 15 to 50 m/s during coughing or shouting. The number of bacteria in a single sneeze varies from 10^4 to 10^6 , and viral numbers can be much higher than this. Because of their small size, the droplets evaporate quickly in the air, leaving behind dried mucus in which the airborne pathogens remain embedded.

The human respiratory tract is divided into upper and lower regions, and specific airborne pathogens tend to exploit one region or the other, or sometimes both (Figure 31.2). The speed at which air moves through the human respiratory tract varies, and in the lower respiratory tract the rate is quite slow. As air slows down, particles in it stop moving and settle. Large particles settle first and the smaller ones later; only particles smaller than about 3 μm travel as far as the bronchioles in the lower respiratory tract (Figure 31.2).

Upper respiratory infections such as the common cold are typically acute and non-life-threatening. By contrast, lower respiratory infections, such as bacterial or viral pneumonia, are often chronic and can be quite serious, especially in elderly or immunocompromised individuals. Also, although most common respiratory infections are not serious in an otherwise healthy host, they can set the stage for *secondary infections* that can be life-threatening. For example, death of an elderly person from pneumonia following a severe case of influenza is not an uncommon event.

Most human respiratory pathogens are transmitted from person to person because humans are the only reservoir for the pathogens. However, many airborne pathogens, such as *Streptococcus* spp., cold viruses, and influenza, can also be transmitted by direct contact (for example, by a handshake) or on fomites. Accurate and rapid diagnosis and treatment of respiratory infections are well developed in the clinical setting and, if practiced effectively, can limit

host damage. Many bacterial and viral pathogens transmitted by an airborne route can be controlled by immunization, and most respiratory bacterial pathogens respond readily to antibiotic therapy. Antiviral therapies, on the other hand, are rather limited, and recovery from viral infections is often due solely to the immune response.

Check Your Understanding

- Why can it be said that respiratory pathogens have exploited an effective means of transmission?
- Identify pathogens more commonly found in the upper respiratory tract. Identify pathogens more commonly found in the lower respiratory tract.

31.2 Streptococcal Syndromes

Streptococcal diseases are transmitted by airborne droplets or by direct contact, and the species *Streptococcus pyogenes* (Figure 31.3) and *Streptococcus pneumoniae* are the most important human respiratory pathogens. Streptococci are nonsporulating, homofermentative but aerotolerant gram-positive cocci (◀ Section 16.6). Cells of *S. pyogenes* typically grow in elongated chains (Figure 31.3), as do many other species of the genus. Pathogenic strains of *S. pneumoniae* grow in pairs or short chains, and virulent strains produce an extensive polysaccharide capsule (see Figure 31.11). Virulent strains of *Streptococcus* can form vicious purulent (pus-forming) wounds in humans and other warm-blooded (endothermic) animals (Figure 31.4 and see Figure 31.10). Many other serious conditions whose symptoms are less dramatic than these are also associated with streptococcal infections.

Streptococcus pyogenes

Streptococcus pyogenes (Figure 31.3), the major species in the group A streptococci, is frequently isolated from the upper respiratory tract of healthy adults. Although numbers are typically low, serious infections are possible if host defenses are weakened or a new, highly virulent strain is encountered.

S. pyogenes is the cause of streptococcal pharyngitis, better known as strep throat (Figure 31.5). Most clinical isolates of *S. pyogenes* produce an exotoxin (◀ Sections 25.6 and 25.7) that lyses red blood

Figure 31.3 *Streptococcus pyogenes*. (a) Gram stain of cells of *Streptococcus pyogenes*. Cells grow in chains and range in size from 0.6 to 1 μm in diameter. (b) Computer-generated image of a scanning electron micrograph of cells of *S. pyogenes*.

Figure 31.4 Pus-forming wound from β -hemolytic streptococci. (a) Pus and coagulated blood from a *Streptococcus equi* infection of a horse's salivary glands (the salivary glands have burst open from the infection). (b) Colonies of *S. equi* showing β -hemolysis on blood agar (compare with Figure 31.8). (c) Phase-contrast photomicrograph of cells of *S. equi*. Cells are 1 μ m in diameter.

cells in culture media, a condition called β -hemolysis (Figure 31.4b and see Figure 31.8). Streptococcal pharyngitis is characterized by a severe sore throat, enlarged tonsils with red spots on the soft palate (Figure 31.5), tender cervical lymph nodes, and a mild fever and feeling of general malaise. *S. pyogenes* can also cause infections of the middle ear (*otitis media*) and of the mammary glands (*mastitis*); infections of the superficial layers of the skin called *impetigo* (Figure 31.6); *erysipelas*, an acute streptococcal skin infection (Figure 31.7); and other conditions linked to the aftereffects of streptococcal infections.

Figure 31.5 A case of strep throat caused by *Streptococcus pyogenes*. The back of the throat is inflamed and shows small red spots, typical of streptococcal pharyngitis.

Figure 31.6 Typical lesions of impetigo. Impetigo is commonly caused by *Streptococcus pyogenes* or *Staphylococcus aureus*.

About half of the clinical cases of severe sore throat are due to *S. pyogenes*; most others are due to viral infections. Because of this, an accurate and rapid diagnosis of a severe sore throat is important. If the sore throat is due to *S. pyogenes*, immediate treatment is important because untreated group A streptococcal infections can lead to serious secondary diseases such as scarlet fever (see Figure 31.9), rheumatic fever, acute glomerulonephritis, and streptococcal toxic shock syndrome. On the other hand, if the sore throat is due to a virus, treatment with antibiotics will be useless and will only promote drug resistance on the part of the normal microbiota.

Clinical tools for quickly diagnosing strep throat are widely available and in routine use in primary care clinics. These tools include, in particular, rapid antigen detection systems that contain antibodies specific for cell surface proteins of *S. pyogenes* (Section 29.7 and Figure 29.21). A more sensitive and accurate confirmation is possible by obtaining an actual culture of *S. pyogenes* from the throat or other suspected lesion on a blood agar plate (Figure 31.8). In contrast to rapid tests, however, results of a throat culture may take up to 48 h to process, and such a delay in treatment can have adverse effects, as we consider now.

Scarlet and Rheumatic Fevers and Other Group A Streptococcal Syndromes

Certain strains of group A streptococci carry a lysogenic bacteriophage that encodes streptococcal pyrogenic exotoxin A (SpeA), SpeB, SpeC, and SpeF. These exotoxins are responsible for most of the symptoms of *streptococcal toxic shock syndrome* and *scarlet fever* (Figure 31.9). Streptococcal pyrogenic exotoxins are superantigens that activate and recruit large numbers of T cells to the infected tissues (Sections 25.7 and 28.2). Toxic shock results when the activated T cells secrete cytokines, which in turn activate large numbers of macrophages and neutrophils, causing severe inflammation and tissue destruction.

ODC/Dr. Thomas F. Sellers

Figure 31.7 Erysipelas. Erysipelas is a *Streptococcus pyogenes* infection of the dermis, shown here on the nose and cheeks, characterized by redness and distinct margins of infection. Other commonly infected body sites include the ears and the legs.

Scarlet fever, signaled by a severe sore throat, fever, and characteristic rash (Figure 31.9), is readily treatable with antibiotics or may be self-limiting. But treatment is always advisable because several undesirable conditions can emerge from a case of scarlet fever. Occasionally group A streptococcal infections cause fulminant (sudden and severe) invasive systemic infections, such as cellulitis, a skin infection in subcutaneous layers; or *necrotizing fasciitis*, a rapid and progressive disease resulting in extensive destruction of subcutaneous tissue, muscle, and fat (Figure 31.10). Necrotizing fasciitis is a clinical term for the condition caused by “flesh-eating bacteria.” In these cases, SpeA, SpeB, SpeC, and SpeF exotoxins and the bacterial cell surface M protein function as superantigens; the associated host inflammation results in extensive tissue destruction and can be fatal (Figure 31.10).

Untreated or insufficiently treated *S. pyogenes* infections may lead to other severe conditions 1 to 4 weeks after the onset of infection.

Franklin H. Top

Figure 31.9 Scarlet fever. The typical rash of scarlet fever results from the activity of the pyrogenic exotoxins produced by *Streptococcus pyogenes*.

For example, the immune response to the invading pathogen can produce antibodies that cross-react with host tissue antigens of the heart, joints, and kidneys, resulting in damage to these tissues. The most serious of these syndromes is **rheumatic fever** caused by rheumatogenic strains of *S. pyogenes*. These strains contain cell surface antigens that are similar in structure to heart valve and joint proteins. Thus, rheumatic fever is, in effect, an *autoimmune* complication (◀ Section 28.1) because antibodies directed against streptococcal antigens cross-react with heart valve and joint antigens, causing inflammation and tissue destruction. Damage to host tissues may be permanent and is often exacerbated by subsequent streptococcal infections that lead to recurring bouts of rheumatic fever. Another streptococcal syndrome is *acute poststreptococcal glomerulonephritis*, a painful kidney disease. This “immune complex” disease develops transiently when streptococcal antigen–antibody complexes in the blood lodge in the glomeruli (filtration membranes of the kidney) and cause inflammation, a serious condition called *nephritis*.

Streptococcus pneumoniae

A second major human streptococcal pathogen is *Streptococcus pneumoniae* (Figure 31.11), a species that can cause invasive lung infections, typically as secondary infections to other respiratory disorders. Encapsulated strains of *S. pneumoniae* (Figure 31.11; ◀ Figure 25.4) are particularly virulent because they are especially invasive. Cells invade the lower respiratory tract where the capsule enables the cells to resist phagocytosis yet generate a strong host inflammatory response. Pneumonia results from the accumulation of recruited phagocytic cells and fluid. Cells of *S. pneumoniae* can then spread from the focus of infection as a bacteremia, sometimes infecting the bones, middle ear, and heart valves (endocarditis). *S. pneumoniae* infection is often the cause of death in elderly persons whose death is reported to be from “respiratory failure.”

Unlike the case with *S. pyogenes*, effective vaccines are available for preventing infection by the most common strains of

Michael T. Madigan

Figure 31.8 β -Hemolysis. The ability of a bacterium to lyse red blood cells and form a clear zone around a colony on a blood agar plate indicates secretion of the protein β -hemolysin. See also Figures 25.17a and 31.4b.

Figure 31.10 Necrotizing fasciitis (flesh-eating bacteria). Soft tissue infection of human hip and thigh by group A *Streptococcus pyogenes*. The flesh has split open to reveal muscle tissues.

S. pneumoniae. An older vaccine widely used in adults consisted of a mixture of 23 capsular polysaccharides from the most prevalent pathogenic strains. The vaccine is recommended for those over age 60, healthcare providers, individuals with compromised immunity, and any other high-risk population. A newer conjugate vaccine (◀ Figure 28.9) called PREVNAR 13® is an update of the traditional vaccine. It is effective against the 13 *S. pneumoniae* strains most commonly seen today and is recommended for adults age 50 or older.

S. pneumoniae infections typically respond quickly to penicillin therapy, but up to 30% of pathogenic isolates now exhibit resistance to this drug. Resistance to the antibiotics erythromycin and cefotaxime is also found in some strains, but thus far, all strains have been found sensitive to vancomycin, an antibiotic held in reserve for treating pneumonia and several other bacterial diseases where antibiotic resistance is widespread (◀ Section 28.7).

Figure 31.11 *Streptococcus pneumoniae*. India ink negative stain of cells of *Streptococcus pneumoniae*. An extensive capsule surrounds the cells, which are 1.0–1.2 μm in diameter.

Figure 31.12 *Corynebacterium diphtheriae*, the causative agent of diphtheria. (a) Cells of *C. diphtheriae* showing typical club-shaped appearance. The gram-positive cells are 0.5–1 μm in diameter and may be several micrometers in length. (b) Colonies of *C. diphtheriae* grown on a selective medium of blood agar plus tellurite.

Check Your Understanding

- How does *Streptococcus pyogenes* infection cause rheumatic fever, and why is rheumatic fever considered to be an autoimmune complication?
- What is the primary virulence factor for *Streptococcus pneumoniae*?

31.3 Diphtheria and Pertussis

Diphtheria is a severe respiratory disease that typically infects young children. Diphtheria is caused by *Corynebacterium diphtheriae*, a gram-positive, nonmotile, and aerobic club-shaped bacterium that forms small, smooth colonies on blood agar plates (Figure 31.12).

Pertussis, also known as **whooping cough**, is a serious respiratory disease caused by infection with *Bordetella pertussis*, a small, gram-negative, aerobic coccobacillus (see Figure 31.14). As with diphtheria, pertussis mostly affects children but can cause serious respiratory disease in adults as well. Both diphtheria and pertussis can be prevented by vaccination and cured with antibiotics.

Diphtheria

Cells of *C. diphtheriae* (Figure 31.12a) enter the host from airborne droplets, infecting the tissues of the throat and tonsils and typically causing swelling of the neck (Figure 31.13a). Throat tissues respond to *C. diphtheriae* infection by forming a characteristic lesion called a *pseudomembrane* consisting of damaged host cells and cells of *C. diphtheriae* (Figure 31.13b). Not all strains of *C. diphtheriae* cause diphtheria. *Pathogenic* strains of *C. diphtheriae* carry a lysogenic bacteriophage whose genome encodes a powerful exotoxin called *diphtheria toxin*. This toxin inhibits protein synthesis in the host, leading to cell death (◀ Figure 25.13). Death from diphtheria is due to a combination of partial suffocation by the pseudomembrane and tissue destruction by diphtheria exotoxin. *C. diphtheriae* isolated from the throat is diagnostic for diphtheria. Nasal or throat swabs are used to inoculate blood agar containing tellurite (Figure 31.12b) or Loeffler's medium, a selective medium that inhibits the growth of most other respiratory pathogens.

Prevention of diphtheria is accomplished with a highly effective toxoid vaccine, part of the DTP3 or DTaP (diphtheria toxoid, tetanus toxoid, and acellular pertussis) vaccine (◀ Section 28.3). Diphtheria is all but absent from developed countries where this vaccine is

Figure 31.13 Diphtheria. (a) A swollen neck is a common symptom of diphtheria. (b) The pseudomembrane (arrows) in an active case of diphtheria restricts airflow and swallowing and is associated with a severe sore throat.

widely used. Penicillin, erythromycin, and gentamicin are generally effective treatments for diphtheria, but in life-threatening cases, diphtheria antitoxin (an antiserum to diphtheria toxoid produced in horses) may be administered in addition to antibiotic therapy.

Pertussis

Pertussis is an acute, highly infectious respiratory disease. Infants less than 6 months old, who are too young to be effectively vaccinated, have the highest incidence of disease and also have the most severe symptoms. Cells of *B. pertussis* (Figure 31.14) attach to ciliated host cells of the respiratory tract and excrete *pertussis exotoxin*. This potent toxin induces synthesis of cyclic adenosine monophosphate (cyclic AMP, ◀ Figure 7.22), which is at least partially responsible for the events that

Figure 31.14 Bordetella and pertussis. (a) Left, scanning electron micrograph of cells of *Bordetella*; right, Gram-stained cells of *B. pertussis*. Cells of *B. pertussis* are typically coccobacilli 0.4–0.5 μm in diameter and about 1 μm long. (b) Pertussis incidence globally has shown a downward trend for the past two decades, associated with an increased uptake of the DTP3 vaccine. Data are from the WHO.

lead to host tissue damage. *B. pertussis* also produces an endotoxin (◀ Section 25.8), which may induce some of the symptoms of whooping cough. Clinically, whooping cough is characterized by a recurrent, violent cough that can last up to 6 weeks. The spasmodic coughing gives pertussis its common name; a whooping sound results from the patient inhaling deep breaths to obtain sufficient air.

Worldwide, up to 25 million cases and over 150,000 deaths occur each year from pertussis, mostly in developing countries. *B. pertussis* is endemic worldwide, and pertussis remains a problem even in developed countries, usually as a result of inadequate immunization. Globally, there has been a dramatic decrease in the incidence of pertussis since 1980 (Figure 31.14). In 2019, only 145,000 cases of pertussis were reported worldwide as opposed to almost 2 million in 1980. The reduced incidence directly correlates to an increased uptake of the DTP3 vaccine, with WHO data showing that approximately 85% of one-year-olds globally have been immunized against pertussis in 2019. Pertussis is a classic endemic disease (◀ Section 30.1); incidence rises cyclically as populations become susceptible and are exposed to the pathogen. A combination of lax vaccination protocols and the fact that pertussis is a much more common disease than diphtheria have probably fueled the overall higher incidence of pertussis in recent years.

Whooping cough can be treated with ampicillin, tetracycline, or erythromycin, although antibiotics alone do not seem to effect a complete cure, as patients continue to show symptoms and remain infectious for up to 2 weeks after beginning antibiotic therapy. This indicates that the immune response may be as important as antibiotics in ridding the pathogen from the body.

Check Your Understanding

- Contrast the disease symptoms of diphtheria and pertussis.
- What precautions can be taken by parents to reduce the risk of pertussis for infants less than 2 months old?

31.4 Tuberculosis and Leprosy

The famous pioneering microbiologist Robert Koch, the founder of the field of medical microbiology, isolated and described the causative agent of tuberculosis, *Mycobacterium tuberculosis*, in 1882 (◀ Section 1.12). A related species, *Mycobacterium leprae*, causes leprosy (Hansen's disease). Mycobacteria are gram-positive bacteria and share the property of being *acid-fast* because of the waxy mycolic acid constituent of their cell walls (◀ Section 16.11). Mycolic acid allows these organisms to retain the red dye carbol-fuchsin after a mycobacterial smear on a slide is washed in 3% hydrochloric acid in alcohol (Figure 31.15). Colonies of *M. tuberculosis* grow slowly on plates and have a characteristically wrinkled morphology.

Tuberculosis

Tuberculosis (TB) is easily transmitted by the respiratory route, and at one time it was the most important infectious disease of humans. TB kills nearly 1.5 million people

Figure 31.15 Mycobacteria. (a) Acid-fast stained lymph node biopsy from a patient with HIV/AIDS shows cells of *Mycobacterium avium*, a relative of *M. tuberculosis*. Multiple bacilli, stained red with carbol-fuchsin and treated with 3% hydrochloric acid, are evident inside each human cell. The individual rods are about 0.4 μm in diameter and up to 4 μm in length. (b) Colonies of *M. tuberculosis*. The rough, wrinkled surface is typical of mycobacterial colonies.

per year, making it the top infectious disease killer worldwide. About one-third of the world's population has been infected with *M. tuberculosis*, though most do not show active disease because cell-mediated immunity (◀ Section 27.8) plays a critical role in the suppression of active disease after infection.

Tuberculosis can take several forms. TB can be a *primary* infection (initial infection) or *postprimary* infection (reinfection). Primary infection typically results from inhalation of droplets containing *M. tuberculosis*, after which the bacteria settle in the lungs and grow. The host mounts an immune response to *M. tuberculosis*, resulting in the formation of aggregates of activated macrophages, called *tubercles*. Bacteria are found in the sputum of individuals with active disease, and areas of destroyed tissue can be seen in chest X-rays (Figure 31.16). Mycobacteria survive and grow within macrophages in the tubercles, forming granulomas, and if the disease is not controlled, extensive destruction of lung tissue can occur. If the disease reaches this stage, the pulmonary infection is often fatal.

In most individuals infected with *M. tuberculosis*, however, acute disease does not occur; instead, the infection is asymptomatic. Nevertheless, the infection hypersensitizes the individual to *M. tuberculosis* or its products and typically protects the individual against postprimary infections. A diagnostic skin test, called the **tuberculin test**, can detect this hypersensitivity (◀ Figure 28.4), and many healthy adults are *tuberculin-positive* as a result of previous or current inapparent infections. In most cases, the cell-mediated immune response to *M. tuberculosis* is protective and lifelong. However, some tuberculin-positive patients develop postprimary tuberculosis through reinfection from bacteria that have remained dormant in lung macrophages for years. Because of this, individuals who have a positive tuberculin test are typically treated with anti-tuberculosis drugs for extended periods to ensure that all mycobacteria have been killed.

Antimicrobial therapy of TB has been a major means of controlling the disease. Streptomycin was the first effective anti-tuberculosis antibiotic, but the real revolution in tuberculosis treatment came with the discovery of isonicotinic acid hydrazide, called *isoniazid* (INH). This drug is highly effective and readily absorbed when given

orally. Isoniazid is a growth factor analog (◀ Section 28.5 and Table 28.4) of the structurally related molecule nicotinamide; in mycobacteria the drug inhibits mycolic acid synthesis, and this compromises cell wall integrity. Following treatment with isoniazid, mycobacteria lose their acid-fast properties, in keeping with the role of mycolic acid in this staining property.

Treatment of tuberculin-positive individuals is typically achieved with daily doses of isoniazid and the antibiotic rifampin for 2 months, followed by biweekly doses for a total of 9 months. This treatment eradicates pockets of *M. tuberculosis* cells and prevents emergence of antibiotic-resistant derivatives. Multiple drug therapy reduces the possibility that strains having resistance to more than one drug will emerge. Resistance of *M. tuberculosis* to isoniazid and other drugs, however, is increasing, especially in HIV/AIDS patients, in whom TB is a common infection (see Figure 31.46g; see also MicrobiologyNow on the opening page of this chapter). Treatment of these strains, called *multidrug-resistant tuberculosis strains*, requires the use of second-line tuberculosis drugs that are generally more toxic, less effective, and more costly than rifampin and isoniazid. Multiple drug resistance is a major reason the incidence of TB is slowly increasing in developed countries worldwide.

Figure 31.16 Tuberculosis symptoms. (a) Sputum sample from a patient with tuberculosis stained by the Smithwick acridine orange method. Cells of *Mycobacterium tuberculosis* are the yellow-orange rod-shaped structures (arrows). (b) Normal chest X-ray. The faint white lines are arteries and other blood vessels. (c) Chest X-ray showing an advanced case of pulmonary tuberculosis; white patches (arrows) indicate tubercles that are densely populated by viable cells of *M. tuberculosis*.

Figure 31.17 Lepromatous leprosy lesions on the skin. (a) Lepromatous leprosy is caused by infection with *Mycobacterium leprae*. The lesions can contain up to 10^9 bacterial cells per gram of tissue, indicating an active uncontrolled infection with a poor prognosis. (b) The palm of the right hand of a leprosy patient showing the claw-like form and digit deformation characteristic of late-stage leprosy.

Leprosy

Mycobacterium leprae, a relative of *M. tuberculosis*, causes the disease *leprosy*, more formally known as *Hansen's disease*. The most serious form of Hansen's disease is *lepromatous leprosy*, characterized by folded, bulblike lesions on the body, especially on cooler parts of the body such as the face and extremities (Figure 31.17a). The lesions are due to the growth of *M. leprae* cells in skin Schwann cells that insulate the nerves, and the lesions contain large numbers of bacterial cells. Like cells of other mycobacteria (Figure 31.15a), cells of *M. leprae* from the lesions stain deep red with carbol-fuchsin in the acid-fast staining procedure, providing a definitive demonstration of active infection.

In severe untreated cases of leprosy, the disfiguring lesions lead to destruction of peripheral nerves; muscles then atrophy, and motor function is impaired. The loss of sensation in the extremities leads to inadvertent injuries, such as burns and cuts. Loss of bone calcium leads to a slow shrinking of the digits and their transition to claw-like forms in late-stage leprosy (Figure 31.17b). Pathogenicity in the disease is due to a combination of delayed-type hypersensitivity (◀ Section 28.1) and the highly invasive activities of *M. leprae*, which can grow within macrophages and lead to the characteristic lesions (Figure 31.17a). Leprosy is transmitted by direct contact as well as by an airborne route, but it is not as highly contagious as TB. Historically, leprosy has been associated with poverty, malnutrition, and poor sanitation and hygiene. Among other things, these factors undoubtedly affect an individual's ability to resist infection.

Many Hansen's disease patients exhibit less-pronounced lesions from which *M. leprae* cells cannot be obtained; these individuals have the *tuberculoid* form of the disease. Tuberculoid leprosy is characterized by a vigorous immune response and a good prognosis for spontaneous recovery. Hansen's disease of either form, and the continuum of intermediate forms, is treated using a multiple drug therapy protocol, which includes some combination of extended therapy of up to 1 year with *dapsone* (4,4'-sulfonylbisbenzeneamine, an inhibitor of folic acid synthesis); *rifampin*, a bacterial RNA polymerase inhibitor; and *clofazimine*, a drug that targets bacterial respiration and ion transport.

Leprosy is considered a neglected tropical disease by the WHO. In 2019, the WHO stated that 202,000 cases of leprosy were reported

globally, most of which were confined to countries such as India, Brazil, and Indonesia, with more than 10,000 people infected in each. Until recently, a leprosy diagnosis relied on the identification of *M. leprae* cells from lesions. However, a quick, inexpensive, and specific blood test is now available that greatly assists in diagnosing early-stage leprosy, the most treatable form.

In addition to *M. tuberculosis* and *M. leprae*, several other mycobacteria are human pathogens. These include in particular *M. bovis*, a close relative of *M. tuberculosis* and a common pathogen of dairy cattle. *M. bovis* can initiate classic symptoms of TB in humans; however, a combination of the pasteurization of milk and the culling of infected cattle has greatly reduced the incidence of bovine-to-human transmission of this form of TB.

Check Your Understanding

- Why is *Mycobacterium tuberculosis* a widespread respiratory pathogen?
- Describe three common characteristics of pathogenic mycobacteria.

31.5 Meningitis and Meningococcemia

Meningitis is an inflammation of the meninges, the membranes that compose the protective covering of the central nervous system, that is, the spinal cord and brain. Several different microorganisms, including certain viruses, bacteria, fungi, and protists, can cause meningitis. Here we focus on the severe bacterial form of the disease called *infectious meningitis*, caused by the bacterium *Neisseria meningitidis*.

Pathogen and Disease Syndromes

Neisseria meningitidis, often called the *meningococcus*, is a gram-negative and obligately aerobic coccus about $0.6\text{--}1\text{ }\mu\text{m}$ in diameter (Figure 31.18a); it is a relative of the bacterium that causes gonorrhea, *Neisseria gonorrhoeae*. The bacterium is transmitted to a new host, usually via the airborne route from an infected individual, and attaches to the cells of the nasopharynx. Once there, the organism quickly gains access to the bloodstream (bacteremia, ▶ Section 25.2), where it disseminates throughout the body and causes upper respiratory tract symptoms. Meningitis is characterized by the sudden onset of a headache accompanied by vomiting and a stiff neck, and its seriousness is underscored by the fact that meningitis can progress to

Figure 31.18 *Neisseria meningitidis*. The organism causes meningitis and meningococcemia. (a) Gram stain of cells of *N. meningitidis*; cocci are about $0.6\text{--}1\text{ }\mu\text{m}$ in diameter. (b) Four-month-old infant with gangrene on legs from meningococcemia.

coma and death in less than a day. Instead of, or in addition to, full-blown meningitis, *N. meningitidis* bacteremia sometimes leads to fulminant **meningococcemia**, a condition characterized by intravascular coagulation and tissue destruction (gangrene, Figure 31.18*b*), shock, and death in over 10% of cases.

Meningococcal meningitis often occurs in epidemics, usually in populations living in close proximity, such as in military barracks or college dormitories. Anyone can get meningococcal disease, but the incidence is much higher in infants, school-age children, and young adults. Up to 30% of people carry *N. meningitidis* in their nasopharynx with no apparent harmful effects, and the trigger for conversion from the asymptomatic carrier state to the disease state is unknown.

Diagnosis, Treatment, and Vaccines

Meningococcal meningitis is definitively diagnosed from cultures of *N. meningitidis* isolated from nasopharyngeal swabs, blood, or cerebrospinal fluid. Thayer–Martin medium, a selective medium for the growth of pathogenic *Neisseria*, including both *N. meningitidis* and *N. gonorrhoeae* (◀ Figure 29.6), is used to isolate *N. meningitidis*, and colonies containing gram-negative diplococci (Figure 31.18*a*) are further tested. However, due to the rapid onset of life-threatening symptoms in infectious meningitis, preliminary diagnosis is often based on clinical symptoms and treatment is started before culture tests confirm infection with *N. meningitidis*. Treatment is typically with penicillin, and intravenous application is often needed to speed antibiotic infusion.

Naturally occurring antibodies acquired by subclinical infections with *N. meningitidis* are effective for preventing infectious meningitis in most adults. Vaccines consisting of purified polysaccharides or polysaccharides from the most prevalent pathogenic strains are available to immunize certain susceptible populations, including military recruits and students living in dormitories, especially if an outbreak is in progress. In addition, the antibiotic rifampin is often used to eradicate the carrier state and prevent meningococcal disease in close contacts of infected individuals.

- Describe the infection by *Neisseria meningitidis* and the resulting development of meningococcemia.

II • Airborne Viral Diseases

Because viruses are so small, they can linger in the tiniest of vapors emitted from an infected individual. Viral diseases transmitted through the air are some of the most contagious infectious diseases known, ranging from the common cold to serious respiratory infections, such as measles and influenza.

31.6 MMR and Varicella-Zoster Infections

The most prevalent and difficult to treat of all human infectious diseases are those caused by viruses. This is because viruses can often remain infectious for long periods in dried mucus (Figure 31.1) or

on fomites, and because viruses require host cells for replication. Hence, infectious material can be virtually anywhere, and destroying the virus often means killing the cell as well.

Most viral diseases are acute, self-limiting infections, but some can be problematic in healthy adults. We begin with measles, rubella, mumps, and chicken pox, all common, endemic viral diseases transmitted in infectious droplets by an airborne route.

Measles and Rubella

Measles (*rubeola* or *7-day measles*) affects susceptible children as an acute, highly infectious (◀ Table 30.3), often epidemic disease. The measles virus (Figure 31.19*a*) is a *paramyxovirus*, a single-stranded, minus-sense RNA virus (◀ Section 11.9) that enters the nose and throat by airborne transmission, quickly leading to a systemic viremia. Symptoms start with nasal discharge and redness of the eyes. As the disease progresses, fever and cough appear and rapidly intensify, followed by a characteristic rash (Figure 31.19*b, c*).

Symptoms of measles generally persist for 7–10 days, and no drugs are available that will eliminate symptoms. However, the measles virus generates a strong immune response. Circulating antibodies to measles virus are measurable within 5 days of infection; these serum antibodies along with cytotoxic T lymphocytes combine to eliminate the virus from the host. Possible measles postinfection complications include middle ear infection, pneumonia, and, in rare cases, measles encephalomyelitis.

Figure 31.19 Measles in children. (a) Transmission electron micrograph of a measles virus virion; a virion is about 150 nm in diameter. (b, c) Measles rash. The light pink rash starts on the head and neck, and can spread to the chest, trunk, and limbs. Discrete papules coalesce into blotches as the rash progresses for several days.

Although measles was once a common childhood illness, there has been a dramatic reduction in the incidence of measles globally since the introduction of its vaccine in 1963, with case numbers dropping from above 4 million in 1980 to only 170,000 in 2017. The WHO reports that between 2000 and 2018, the measles vaccine saved 23.2 million lives. However, despite the disease being vaccine-preventable, in the past two years there has been an increase in the global number of cases and deaths from measles. Of the over 360,000 cases of measles reported in 2018, there were 140,000 deaths, most of which were children aged under 5. This number rose again in 2019, with over 870,000 cases reported worldwide. There is also the potential for measles cases to rise due to the SARS-CoV-2 pandemic. As healthcare workers have been dealing with SARS-CoV-2 infections, there has been a decrease in childhood vaccinations globally. For example, over 20 countries suspended measles vaccination campaigns during the pandemic.

Worldwide, measles remains endemic, and despite the existence of a highly effective vaccine, the disease still causes about 100,000 annual deaths, mostly in children. Active immunity to measles is conferred with an attenuated virus preparation as part of the MMR (measles, mumps, rubella) vaccine (◀ Section 28.3). Because the disease is highly infectious, all public school systems in the United States require proof of measles immunization before a child can enroll. A childhood case of measles generally confers lifelong immunity.

Rubella (sometimes called *German measles* or *3-day measles*) is caused by a single-stranded, positive-sense RNA virus distinct from that of measles (◀ Section 11.8). Symptoms of rubella resemble those of measles (Figure 31.20) but are often restricted to just the upper torso. Rubella is less contagious than measles, and thus a significant proportion of the population has never been infected. However, during the first three months of pregnancy, rubella virus can infect the fetus by placental transmission and cause serious fetal abnormalities including stillbirth, deafness, heart and eye defects, and brain damage, events called *congenital rubella syndrome*. Thus, women should not be immunized with the rubella vaccine or contract rubella during pregnancy. Also for this reason, routine childhood immunization against rubella should be practiced. A highly effective attenuated rubella virus is administered as part of the MMR vaccine. As a result of a 15-year-long campaign to eliminate rubella in the Western Hemisphere using this vaccine, the Americas have officially become the first region to be declared rubella-free. Public health officials are in the process of extending the rubella vaccination program worldwide, with the ultimate goal being global eradication of the virus.

Mumps

Mumps, like measles, is caused by a paramyxovirus and is also highly infectious by the airborne route. Mumps is spread by airborne

Centers for Disease Control

Figure 31.21 Mumps. Glandular swelling characterizes infection with the mumps virus. Mumps symptoms typically last about one week, and a person is infectious both before and during the symptomatic stages.

droplets, and the disease is characterized by inflammation of the salivary glands, typically the parotid gland, the largest of the salivary glands, leading to swelling of the jaws and neck (Figure 31.21). The virus spreads through the bloodstream and may infect other organs, including the testes and pancreas, and may cause encephalitis in rare cases. As for measles, the immune response rather than drug treatment is what cures a case of mumps. The host immune response produces antibodies to mumps virus surface proteins, and this generally leads to a quick recovery and lifelong immunity to reinfection.

An attenuated mumps vaccine (part of the MMR) is highly effective in preventing disease. Hence, the prevalence of mumps in developed countries is low, with disease generally restricted to individuals who did not receive the vaccine. However, outbreaks of mumps in the United States in 2006, 2016, and 2017 each resulted in more than 6000 annual cases. These outbreaks affected mainly young adults (18–34), and as a result, recommendations for immunizations were revised to target school-age children, healthcare workers, and adults who had not previously had mumps.

Chicken Pox and Shingles

Chicken pox (*varicella*) is a common childhood disease caused by the varicella-zoster virus (VZV), a double-stranded DNA herpesvirus (◀ Section 11.7). VZV is a mild but highly contagious disease and is transmitted by infectious droplets, especially when susceptible individuals are in close contact. In school children, for example, close confinement during the winter months leads to the spread of VZV through airborne droplets from infected classmates and through direct contact with chicken pox blisters of other children or contaminated fomites. The virus enters the respiratory tract, multiplies, and is quickly disseminated via the bloodstream, resulting in a systemic papular rash (Figure 31.22) that heals quickly without scarring. A live-attenuated varicella vaccine was first developed in Japan in the early 1970s, and there are currently several live-attenuated varicella vaccines available, including both a monovalent vaccine and a combined vaccine that protects against measles, mumps, rubella, and varicella. The United States was the first country to introduce the varicella vaccine into its national vaccination program. Currently, over 36 countries worldwide have

CDC/PHIL

Figure 31.22 Chicken pox. Papular rash on the foot of an adult. The papules are due to infection by varicella-zoster virus, the herpesvirus that causes chicken pox.

introduced a varicella vaccine into their national vaccination schedule.

Globally, approximately 95% of individuals aged 50 and over have been infected with VZV at some point in their life. VZV establishes a lifelong latent (permanent) infection in nerve cells. The virus can remain dormant there indefinitely, but in some individuals the virus migrates from this reservoir to the skin surface, often years or decades later, causing a painful skin eruption called *shingles* (*zoster*). Shingles most commonly strikes immunosuppressed individuals or the elderly, causing severe blisters and a rash on the head, neck, or upper torso. A number of shingles vaccines are available worldwide. A moderately effective shingles vaccine containing concentrated attenuated virus (marketed as Zostavax®) is available for individuals over 50 years of age, and it is part of the national immunization schedule in the United Kingdom and Australia. The vaccine stimulates antibody- and cell-mediated immunity to VZV, which keeps VZV from migrating out of nerve ganglia to skin cells and triggering shingles symptoms. A recombinant shingles vaccine marketed as Shingrix® is reported to be nearly 90% effective in preventing a case of shingles (if administered in both primary and booster injections) and is the shingles vaccine recommended by the Advisory Committee on Immunization Practices of the United States Centers for Disease Control and Prevention.

- How do the genomes of the measles virus (rubeola) and the German measles virus (rubella) differ?
- Describe the potential serious outcomes of infection by measles, mumps, rubella, and VZV viruses.
- Identify the effects of immunization on the incidence of measles, mumps, rubella, and chicken pox.

31.7 The Common Cold

Colds are the most common of infectious diseases. Colds are typically upper respiratory tract viral infections that are transmitted via droplets spread from coughs, sneezes, and respiratory secretions. Colds are usually of short duration, lasting a week or so, and the symptoms are milder than other respiratory diseases such as

TABLE 31.1 Colds and influenza		
Symptoms	Cold	Influenza
Fever	Rare	Common (39–40°C); sudden onset
Headache	Rare	Common
General malaise	Slight	Common; often quite severe; can last several weeks
Nasal discharge	Common and abundant	Less common; usually not abundant
Sore throat	Common	Less common
Vomiting and/or diarrhea	Rare	Common in children
Incidence ^a	340	50

^aCases/100 people per year in the United States for recent years. Incidence of all other infectious diseases totals about 30 cases/100 people per year.

influenza. **Table 31.1** contrasts the usually distinct symptoms and incidence of colds and influenza.

Symptoms and Transmission of the Common Cold

Cold symptoms include *rhinitis* (inflammation of the nasal region, especially the mucous membranes), nasal obstruction, watery nasal discharges, muscle aches, and a general feeling of malaise, usually without fever. *Rhinoviruses* are single-stranded plus-sense RNA viruses of the picornavirus group (◀ Section 11.8) and are the most common causes of colds. Over 150 different rhinoviruses have been identified. About one-quarter of all colds are due to infections with other viruses. These include in particular the *adenoviruses* (**Figure 31.23a**) and *coronaviruses* (**Figure 31.23b**). Coxsackie viruses, respiratory syncytial viruses (RSV), and orthomyxoviruses are collectively responsible for only a small percentage of common colds.

Aerosol transmission is a major means of spreading colds, although experiments with volunteers suggest that direct contact and indirect contact involving fomites are also important means of transmission, perhaps even more important than aerosols. Incidence of the common cold rises when people are indoors in the winter months, although it is possible to “catch a cold” at any time of year. Most antiviral drugs are ineffective against common cold viruses, although some have shown promise for preventing the onset of symptoms following rhinovirus exposure. Moreover, new antiviral drugs are being designed based on knowledge of the three-dimensional structure of cold viruses. For example, antirhinovirus drugs that bind to the virus and change its surface properties in such a way as to prevent it from attaching to host cells have been developed. But thus far, most “cold drugs” on the market simply help to reduce the severity of symptoms—primarily the cough, nasal discharges, congestion, and headache.

Treatment

Because colds are generally self-limiting and not serious diseases, treatment is aimed at controlling symptoms, especially nasal discharges, with antihistamine and decongestant drugs. A plethora of such drugs are available without prescription, each touting its superior features. Many of these help control cold symptoms fairly well, but some have unwanted side effects, especially drowsiness. The severity of symptoms of any cold event is a function of the virulence

of the cold virus, the overall health and well-being of the person at the time of infection, and the nature of supportive factors during infection. In the long run, immunity is more important in ridding the body of a cold virus than anything drugs can achieve. Cold viruses induce an antibody-mediated immune response that targets the current cold virus. However, the number of immunologically unique strains of each type of cold virus makes long-term immunity to the common cold unobtainable.

On average, a person in the United States contracts about three colds per year compared with less than one case of influenza per person per year (Table 31.1). This is an indication of the ease of transmission of the common cold and the large number of different viruses that cause the same general symptoms. Thus, the common cold is a recurrent event that humans must simply live with. Preventive measures such as avoiding contact with major common cold fomites (door handles and other surfaces touched by others) and with one's inner nostrils, coupled with frequent hand washing, are best practices for avoiding the common cold.

Check Your Understanding

- Define the cause and symptoms of common colds.
- Discuss the possibilities for effective treatment and prevention of colds.

31.8 Influenza

Influenza is a highly infectious airborne disease of viral origin. Influenza viruses contain a single-stranded, negative-sense, segmented RNA genome surrounded by an envelope composed of protein, a lipid bilayer, and external glycoproteins (**Figure 31.24**; Section 11.9). There are three classes of influenza viruses:

CDC/PHIL, E.L. Palmer, M.L. Martin, and F. Murphy

Figure 31.24 Influenza A virus. The virus contains a single-stranded, negative-sense RNA genome in eight segments; a virion is about 100 nm in diameter. Major factors in the success of influenza virus as a pathogen are antigenic drift and antigenic shift (see Figure 31.26).

influenza A, B, and C. Here we consider only influenza A because it is the most important human pathogen.

Antigenic Drift and Antigenic Shift

Each strain of influenza A virus can be identified by a unique set of surface glycoproteins. These glycoproteins are *hemagglutinin* (HA or the “H antigen”) and *neuraminidase* (NA or the “N antigen”). Each virus has one type of HA and one type of NA on its viral capsid and is named for the antigens it contains; for example, “H1N1.” The HA antigen is important in *attaching* the influenza virus to host cells, while the NA antigen is instrumental in *releasing* the virus from host cells; each antigen is composed of several individual proteins (**Figure 31.25**).

Infection or immunization with influenza virus results in the production of antibodies that react with the HA and NA glycoproteins.

Irene T. Schulze

Figure 31.25 Influenza virus structure. Major viral coat proteins are: HA, hemagglutinin (three copies make up the HA coat spike); NA, neuraminidase (four copies make up the NA coat spike); M, coat protein; NP, nucleoprotein; PA, PB1, PB2, and other internal proteins, some of which have enzymatic functions.

When these antibodies bind to HA or NA, the virus is blocked from either attaching or releasing and is effectively neutralized, stopping the infection process. However, over time, the viral genes encoding the HA and NA glycoprotein antigens mutate, rendering minor changes to their amino acid sequence and hence antigenic structure. Mutations that alter as few as one amino acid in the glycoprotein can affect how an antibody binds to these antigens. This slight variation in the structure of influenza viral surface antigens is at the heart of a phenomenon in influenza biology called **antigenic drift**. As a result of these subtle yet important changes, host immunity to a given virus strain diminishes as the strain mutates, and reinfection with the mutated strain can occur. This phenomenon is why last year's influenza vaccine may work only poorly against this year's crop of influenza viruses (**Figure 31.26a**).

In addition to antigenic drift, there is a second feature of influenza virus biology that aids virulence. The single-stranded RNA genome of influenza viruses is *segmented*, with genes found on each of eight distinct segments (◀ **Figure 11.24b**). During virus maturation in the host cell, the viral RNA segments are packaged randomly. To be infective, a virus must be packaged so it contains one copy of each of the eight gene segments. Occasionally, however, more than one strain of influenza virus infects a single animal at one time. In such cases, if the two strains infect the same cell, both viral genomes are replicated; when genome packaging occurs, the segments from

the two strains may intermix. The result is a genetically unique virus that is now a *new virus strain*. This mixing of gene fragments between different strains of influenza virus is called **reassortment**.

Unique *reassortant viruses* trigger the phenomenon known as **antigenic shift** (**Figure 31.26b**), a major change in a surface antigen resulting from the total replacement of the RNA that encoded it. Antigenic shift can immediately and completely change one or both of the major HA and NA viral glycoproteins in a major way. As a result, reassortant viruses are essentially unrecognized by immune responses to previous influenza infections. Reassortant viruses also frequently display one or more unique virulence properties that help to trigger unusually strong clinical symptoms and are the usual catalysts of influenza *pandemics*, which we consider shortly.

Symptoms and Treatment of Influenza

Human influenza virus is transmitted from person to person through the air, primarily in droplets expelled during coughing and sneezing (**Figure 31.1**). The virus infects the mucous membranes of the upper respiratory tract and occasionally invades the lungs. Symptoms include a low-grade fever lasting up to a week, chills, fatigue, head and muscle aches, a cough and/or a sore throat, and general malaise (**Table 31.1**). Most of the serious consequences of seasonal influenza occur not from

(a) **Antigenic drift**

(b) **Antigenic shift**

Figure 31.26 Antigenic drift and antigenic shift in influenza virus biology. (a) Antigenic drift. A new vaccine is prepared each year against the major strain of influenza circulating among the population. However, vaccine efficacy wanes with time as immunologically new surface antigens appear from mutations in genes encoding viral surface proteins. (b) Antigenic shift. Influenza strains that originate in birds and humans can also infect certain other animals, such as swine, and may cause a reassortment of viral genetic material. For example, if a pig becomes infected with both bird and human viruses simultaneously, the viral genomes can be mixed, forming reassortant viruses. If such viruses, which now contain several unique antigens, infect humans, influenza pandemics can be triggered because of an ineffective immune response (◀ **Section 30.8**).

Figure 31.27 An influenza pandemic. Map of the Asian influenza pandemic of 1957. Lax agricultural practices with poultry and swine coupled with human interactions with these animals allowed the reassortment of influenza viral genomes from the three host species, producing a new strain for which there was no immune memory in humans. See Section 30.8 for more coverage of influenza pandemics.

the disease itself but from bacterial secondary infections, especially in persons whose resistance has been lowered by the influenza infection. For example, in infants and the elderly, influenza can be followed by bacterial pneumonia (Section 31.2), sometimes in fatal form.

Most individuals develop protective immunity to the infecting strain of influenza virus, making it impossible for that strain or a very closely related strain to cause widespread infection (an epidemic) until the virus encounters another susceptible population. Immunity occurs from both antibody- and cell-mediated immune responses directed at HA and NA glycoproteins. Influenza epidemics can be controlled by immunization. Developing an effective vaccine, however, is complicated by the large number of existing influenza viral strains resulting from antigenic drift and antigenic shift (Figure 31.26). Through careful worldwide surveillance, samples of the major emerging strains of influenza virus are obtained each year before the onset of seasonal epidemics and used to prepare that year's vaccine. In most years, this approach confers adequate protective immunity, but sometimes the vaccine is only marginally effective. For example, those who received the vaccine during the 2017–18 flu season were only 36% less likely to contract influenza than those who received no vaccine. There is evidence, however, that the annual vaccine does lessen the severity of symptoms and shorten the duration of disease in those who do become ill.

Most human influenza viruses respond to antiviral drugs. The adamantanes—*amantadine* and *rimantadine*—are synthetic amines that inhibit viral replication, and the neuraminidase inhibitors *oseltamivir* (Tamiflu®) and *zanamivir* (Relenza®) (◀ Table 28.5) block release of newly replicated human influenza virions. These drugs are often used early on to shorten the course and severity of infection, especially in the elderly and immunocompromised.

Influenza Pandemics

Influenza pandemics—worldwide epidemics—are much less frequent than outbreaks and epidemics, occurring from 10 to 40 years apart (◀ Section 30.8). Flu pandemics result from antigenic shift,

and virtually all have been due to avian and human influenza viruses reassorting in swine (Figure 31.26b) because swine can propagate both avian and human influenza viruses. This results in a highly virulent influenza strain for which there is no preexisting immunity in humans.

The “Spanish flu” pandemic of 1918 was the most catastrophic in recorded history, and the extreme virulence of the 1918 H1N1 virus is thought to have triggered host production and release of unusually large amounts of inflammatory substances, resulting in systemic inflammation and more severe symptoms than those typical of yearly flu epidemics. The 1957 Asian flu was also a significant pandemic (Figure 31.27), beginning in China and spreading to the United States and shortly thereafter to Europe and South America. In this case, the pandemic influenza strain was a highly virulent H2N2 virus, differing antigenically from all previous strains. Pandemic influenza A (H1N1) 2009 virus, nicknamed the “swine flu,” spread much more rapidly in 2009 than even the 1957 Asian flu, starting in Mexico and spreading quickly to the United States, Europe, and

Central and South America. H1N1 was a classic case of influenza virus genome reassortment in swine (Figure 31.26b), and from the swine reservoir, a highly virulent virus emerged to infect humans. Influenza A H5N1, nicknamed the “bird flu,” emerged in Hong Kong in 1997, and is the major virus health officials are monitoring closely today. H5N1 has been detected in birds in many countries, and if this virus were to infect swine and form an easily transmissible reassortant virus that subsequently jumps to humans (Figure 31.26b), such a virus could initiate a very deadly influenza pandemic.

Check Your Understanding

- Distinguish between antigenic drift and antigenic shift in influenza.
- Discuss the possibilities for effective immunization programs for influenza and compare them to the possibilities for immunization for colds.

III • Direct-Contact Bacterial and Viral Diseases

Several infectious diseases are spread from person to person or from fomites or animals to people through direct nonsexual contact. These diseases range from local infections, such as those caused by *Staphylococcus aureus*, to serious systemic infections associated with high mortality, such as that caused by Ebola virus.

Some pathogens are spread primarily by direct contact with an infected person or by direct contact with blood or excretions from an infected person. Many of the respiratory diseases we have just discussed can also be spread by direct contact, but here we consider diseases spread primarily through direct contact with infected

Figure 31.28 *Staphylococcus aureus* and *S. aureus* infections. Cells divide in several planes, giving the appearance of a cluster of grapes. (a) Gram stain; an individual coccus is about 1 μm in diameter. (b) Scanning electron micrograph of cells. (c) Structure of a boil. Staphylococci initiate a localized skin infection and become walled off by coagulated blood and fibrin through the activity of the enzyme coagulase, a major virulence factor. The ruptured boil releases pus, consisting of dead host cells and bacteria. See also Figure 31.29.

individuals rather than by an airborne route. These include staphylococcal infections, gastric ulcers, certain types of hepatitis, and the highly dangerous Ebola hemorrhagic fever.

31.9 *Staphylococcus aureus* Infections

The genus *Staphylococcus* contains pathogens of humans and other animals. Staphylococci commonly infect skin and wounds and may also cause pneumonia. Most staphylococcal infections result from the transfer of staphylococci in the normal microbiota of an infected, asymptomatic individual to a susceptible individual. Others result from toxemia following the ingestion of contaminated food ("staph food poisoning," ► Section 33.8).

Staphylococci are nonsporulating, gram-positive cocci about 0.5–1.5 μm in diameter that divide in multiple planes to form irregular clusters of cells (Figure 31.28a, b). They are resistant to drying and tolerate high concentrations of salt (up to 10% NaCl) when grown on artificial media. Staphylococci are readily dispersed in dust particles through the air and on surfaces. In humans, two species are important: *Staphylococcus epidermidis*, a nonpigmented species usually found on the skin or mucous membranes, and *Staphylococcus aureus*, a yellow-pigmented species. Both species are potential pathogens, but *S. aureus* is more commonly associated with human

disease. Both species are frequently present in the normal microbiota of the upper respiratory tract and the skin (Figure 31.2 and see Figure 31.30b), making many people potential carriers (◀ Sections 30.1 and 30.3).

Epidemiology and Pathogenesis

Staphylococcal diseases include acne, boils, pimples, impetigo, pneumonia, osteomyelitis, carditis, meningitis, and arthritis. Many of these diseases are *pyogenic* (pus-forming; Figure 31.28c and Figure 31.29). Those strains of *S. aureus* that cause human disease produce a variety of potent virulence factors (◀ Section 25.3). At least four different *hemolysins* (proteins that lyse red blood cells, see Figure 31.8) have been recognized, and a single strain often produces several. A key virulence factor produced by *S. aureus* is *coagulase*, an enzyme that converts the soluble blood glycoprotein fibrinogen to an insoluble protein, fibrin, forming a localized clot (◀ Figure 25.12b). Clotting induced by coagulase results in the accumulation of fibrin around the bacterial cells, making it difficult for host immune cells to contact the bacteria and initiate phagocytosis (◀ Section 26.7). Most *S. aureus* strains also produce *leukocidin*, a protein that destroys white blood cells. Production of leukocidin

(a)

(b)

Figure 31.29 Pus-forming staphylococcal wounds. (a) A typical pus-forming wound on the hand. Pus lies just under the epidermal layer. (b) Abscess on the hand caused by a methicillin-resistant strain of *Staphylococcus aureus* (MRSA strain). If no treatment for a pus-forming wound is sought or if penicillin is administered first, MRSA infections can cause extensive tissue destruction, as shown here.

in skin lesions such as boils and pimples results in host cell destruction and is one of the factors responsible for pus accumulation (Figures 31.28 and 31.29). Some strains of *S. aureus* also produce other virulence proteins, including *hyaluronidase*, *fibrinolysin*, *lipase*, *ribonuclease*, and *deoxyribonuclease*.

Staphylococcus aureus Toxic Shock

S. aureus can also cause **toxic shock syndrome (TSS)**, a serious outcome of certain staphylococcal infections characterized by high fever, rash, vomiting, diarrhea, and in some cases, death. TSS was first recognized in women and was associated with the use of highly absorbent tampons, where conditions in the vagina promoted growth of toxic shock strains of *S. aureus*. However, today, TSS is seen in both men and women and is typically triggered by staphylococcal infections following surgery.

The symptoms of TSS result from an exotoxin (◀ Section 25.6) called *toxic shock syndrome toxin-1*. This very potent exotoxin is a superantigen (◀ Sections 25.7 and 28.2) that is released during cell growth and recruits large numbers of T cells to the site of infection. These then cause a major inflammatory response that is fatal in about 70% of cases. TSS can also result from superantigen exotoxins secreted by other pathogens, including *Streptococcus pyogenes*, the causative agent of several streptococcal syndromes (Section 31.2).

Diagnosis and Treatment and the MRSA Epidemic

To diagnose an *S. aureus* infection through laboratory culture, a specimen, typically from a pus-forming wound (Figure 31.29a), is cultured on a selective and differential medium containing 7.5% NaCl, mannitol, and phenol red, a pH indicator (mannitol–salt agar, **Figure 31.30**). The salt inhibits the growth of nonhalotolerant bacteria while allowing the halotolerant (◀ Section 4.15) staphylococci to grow. In addition, because *S. aureus* ferments mannitol, it generates acidity that changes the medium from red to yellow; other staphylococci, such as *S. epidermidis*, do not (Figure 31.30).

In clinical laboratories, the polymerase chain reaction (PCR, ▶ Section 12.1) is used to amplify genes unique to *S. aureus* from DNA isolated directly from a clinical sample (▶ Section 29.8), and this allows for a quicker diagnosis; results from a laboratory culture

take 24 h. For specific identification of methicillin-resistant strains of *S. aureus* (MRSA), a special selective and differential medium is available (see Explore the Microbial World, “MRSA—A Formidable Clinical Challenge” in Chapter 29), as well as a PCR protocol that identifies *mecA* (the gene that encodes methicillin resistance in MRSA strains) and a rapid immunological test where cells of *S. aureus* in suspension are agglutinated by antibodies to specific cell surface proteins (◀ Figure 29.16).

Historically, *S. aureus* infections have been treated with various penicillin and cephalosporin antibiotics. However, extensive use of these antibiotics for many years has selected for resistant strains that now predominate, especially in the clinical environment. Surgical patients, for example, may acquire staphylococci from healthcare personnel who are asymptomatic carriers of drug-resistant strains. As a result, appropriate antimicrobial drug therapy for *S. aureus* infections is a major problem in healthcare environments. The antibiotics clindamycin and various tetracycline drugs are currently used to treat MRSA infections.

MRSA infections (Figure 31.29b) are becoming more common. Over 80,000 cases of MRSA are reported each year in the United States, but infections are actually probably closer to ten times this number. Many of these cases are hospital-acquired (nosocomial) MRSA (▶ Section 29.2), but many others are not. Because of the potential severity of MRSA infections, it is important to rapidly identify these strains in clinical specimens so that an effective treatment is begun as soon as possible. Delayed treatment of a MRSA infection, whether due to hesitation to seek treatment or treatment with an ineffective antibiotic, can lead to extensive tissue damage (Figure 31.29b).

Prevention of staphylococcal infections is virtually impossible because many people are asymptomatic carriers of *S. aureus*, either on their skin or in their upper respiratory tract. However, identification and treatment of MRSA-carrying healthcare providers who serve in surgical or nursery units has helped limit transmission of these very aggressive strains. As is true of many direct-contact diseases, MRSA transmission can also be greatly diminished by practicing good basic hygiene, avoiding contact with the personal items (including clothing and towels) of others, keeping wounds covered, and for those in the healthcare profession, following the established practices of clinical microbiology safety (▶ Section 29.1).

Check Your Understanding

- What is the normal habitat of *Staphylococcus aureus*? How does *S. aureus* spread from person to person?
- What is MRSA, and why is it a health problem?

Figure 31.30 Mannitol–salt agar in the isolation of staphylococci. (a) Mannitol–salt agar (MSA) is both selective and differential for staphylococci. The presence of 7.5% NaCl makes MSA selective and phenol red makes it differential. Left, *Staphylococcus epidermidis*; right, *Staphylococcus aureus*. (b) A nasal swab of the senior author of this text supports the observation that most humans are carriers of *S. aureus*.

31.10 Helicobacter pylori and Gastric Diseases

Helicobacter pylori is a gram-negative, highly motile and spiral-shaped bacterium (**Figure 31.31**) associated with gastritis, ulcers, and gastric cancers. This bacterium colonizes the non-acid-secreting mucosa of the stomach and the upper intestinal tract. It is estimated that half the world’s population is chronically infected with *H. pylori*. Up to 80% of gastric ulcer patients have concomitant *H. pylori* infections, and up to 50% of asymptomatic adults in developing countries are

Figure 31.31 *Helicobacter pylori*. Colorized scanning electron micrograph of cells attached to the mucous lining of the stomach. Cells range in length from 3 to 5 μm and are about 0.5 μm in diameter. Note the flagella.

chronically infected. Although there is no known nonhuman reservoir of *H. pylori*, infection occurs at high incidence within families, suggesting person-to-person transmission. *H. pylori* infections also occasionally occur in clusters, suggesting that transmission from common sources such as food or water is also possible.

The *Helicobacter* Infection Process

H. pylori is only slightly invasive and colonizes the surfaces of the gastric mucosa, where it is protected from the effects of stomach acids by the gastric mucus layer. Cells of *H. pylori* reach these relatively protected regions by employing a chemoreceptor (◀ Sections 2.11 and 7.6) that tracks the gradient of urea produced by gut epithelia to direct flagellar rotation up the gradient. The organism is strongly ureolytic and cleaves the urea into ammonia and bicarbonate, which help buffer the region of cell colonization from stomach acids (ammonia is a strong base).

After *H. pylori* cells colonize the mucosa, a combination of virulence factors and host responses cause inflammation, tissue destruction, and ulceration. Pathogen products such as the cytotoxin VacA (an exotoxin), urease, and an autoimmune response triggered by *H. pylori* lipopolysaccharide all contribute to localized tissue destruction and ulceration. Individuals who acquire *H. pylori* tend to have chronic infections unless they are treated with antibiotics. Treatment is both straightforward and important, as chronic inflammation of the gastroduodenum (gastritis) due to untreated *H. pylori* infection may lead to the development of gastric cancers.

H. pylori and Clinical Disease

Clinical signs of *H. pylori* infection include belching and stomach (epigastric) pain. Definitive diagnosis requires the isolation or observation of *H. pylori* from a gastric ulcer biopsy. However, a simple diagnostic test for the *H. pylori* enzyme urease is used for a non-invasive diagnosis. In this test, a small amount of ^{13}C - or ^{14}C -labeled urea ($\text{H}_2\text{N}-\text{CO}-\text{NH}_2$) is ingested; if *H. pylori* is present, the

bacterium will hydrolyze the urea, forming labeled CO_2 and ammonia. Hence, the presence of labeled CO_2 in the patient's breath is highly suggestive of *H. pylori* infection.

The best evidence for a causal association between *H. pylori* and gastric ulcers comes from antibiotic treatments for the disease. Long-term treatment with antacids helps alleviate gastric ulcer symptoms temporarily, but most patients relapse within 1 year. However, by treating the *cause* rather than the *effect* of the disease, actual cures can be obtained. *H. pylori* infection is typically treated with a combination of drugs, including the antibacterial compound metronidazole, an antibiotic such as tetracycline or amoxicillin, and a bismuth-containing antacid preparation. The combination treatment, administered for 14 days, abolishes the *H. pylori* infection and provides a true cure.

Like the link with gastric ulcers, the link between *H. pylori* infection and certain forms of gastric cancers, in particular, gastric adenocarcinoma (the most prevalent form of gastric cancer), is also strong. Gastric cancers are the second leading cause of cancer deaths worldwide. Although how *H. pylori* infection actually triggers adenocarcinomas is unclear, it is believed that long-term inflammation caused by infection with this bacterium coupled with host and possibly environmental factors combine to predispose an individual to stomach malignancies. For their contributions to unraveling the connection between *H. pylori* and peptic and duodenal ulcers, the Australian scientists Robin Warren and Barry Marshall were awarded the 2005 Nobel Prize in Physiology or Medicine.

31.11 Hepatitis

Hepatitis is a liver inflammation, commonly caused by an infectious agent. Hepatitis sometimes results in acute illness followed by destruction of functional liver anatomy and cells, a condition known as **cirrhosis**. Hepatitis due to infection can cause chronic or acute disease, and some forms lead to liver cancer.

Although many viruses and a few bacteria can cause hepatitis, a restricted group of viruses is often associated with liver disease. Hepatitis viruses A, B, C, D, and E are phylogenetically diverse viruses (Table 31.2) but share in common their ability to infect the liver, with hepatitis viruses A, B, and C accounting for the majority of cases worldwide. The incidence of hepatitis A and B has decreased significantly over the past 25 years, primarily because of the availability of effective vaccines and increases in surveillance (Figure 31.32). By comparison, with no vaccine available, hepatitis C infections have gradually risen in recent years, although those infected can be cured of infection with HCV-specific drugs.

Hepatitis A and E viruses, although occasionally transmitted person to person, are more commonly transmitted enterically by contaminated food or water. We cover hepatitis A viral disease in Chapter 33. Here our focus is on hepatitis viruses transmitted by direct contact, with the major focus on hepatitis B, the causative agent of “bloodborne hepatitis.”

^aExamples and discussion of each of these genomes can be found in Chapter 11 (◀ Figures 11.2 and 11.3).

Epidemiology

Infection with *hepatitis B virus* (HBV) is called bloodborne hepatitis (or serum hepatitis) because it is transmitted in blood or in body fluids in contact with blood. HBV is a hepadnavirus, a partially double-stranded DNA virus (◀ Section 11.11). The mature virus particle containing the viral genome is called a *Dane particle* (Figure 31.33). HBV causes acute, often severe disease that can lead to liver failure and death. Chronic HBV infection can lead to cirrhosis and liver cancer.

HBV is transmitted by a *parenteral route*, which means “outside the gut.” The main means of HBV transmission is from blood transfusions, contact with infected blood in a hypodermic needle, and from mother to child during childbirth. HBV may also be transmitted through exchanges of body fluids during sex. The number of new HBV infections has remained low and more or less constant since the year 2000 (Figure 31.32). Nevertheless, over 100,000 people worldwide and nearly 5000 people in the United States die yearly from liver failure or liver cancer caused by chronic HBV infection.

Hepatitis D virus (HDV) is a *defective virus* (◀ Section 9.7) that lacks genes encoding its own capsid. HDV is also transmitted by parenteral routes, but because it is a defective virus, it cannot replicate and form an intact virion unless the cell is also infected with HBV. The HDV genome replicates independently but relies on HBV to produce capsid proteins (which are the same as those used by HBV) to form infectious virions. Thus, HDV infections are always

coinfections with HBV, and therefore the HBV vaccine also indirectly protects against HDV.

Hepatitis C virus (HCV) is also transmitted parenterally, most commonly by sharing of needles and syringes for injection of illicit drugs. HCV generally produces a mild or even asymptomatic disease at first, but later up to 85% of those infected develop chronic hepatitis, with up to 20% proceeding to chronic liver disease and cirrhosis. Chronic infection with HCV leads to hepatocarcinoma (liver cancer) in 3–5% of infected individuals. The latency period for development of cancer can be several decades after the primary infection. Only a fraction of the estimated 25,000 annual new infections with HCV in the United States are recognized and formally reported (Figure 31.32). Large numbers of HCV-related deaths occur annually as a result of chronic HCV infections that develop into liver cancer. HCV-induced liver disease accounts for up to 10,000 of the 25,000 annual deaths due to liver cancer, other chronic liver diseases, and cirrhosis.

Other Aspects of Hepatitis Syndromes

Hepatitis is an acute disease of the liver, a vital organ that plays a role in several key metabolic processes, including carbohydrate, lipid, and protein syntheses, as well as detoxification and many other functions. Symptoms of hepatitis include fever, jaundice (yellowing of the skin and the whites of the eyes, Figure 31.33b), and liver enlargement and cirrhosis. All hepatitis viruses cause similar acute symptoms and cannot be readily distinguished based on clinical findings alone. Chronic hepatitis infections, usually caused by HBV or HCV, are often asymptomatic or produce very mild symptoms, but nonetheless cause serious liver disease, even in the absence of liver cancer.

Diagnosis of hepatitis is based on a combination of clinical symptoms and laboratory tests that assess liver function, especially key liver enzymes. Cirrhosis is diagnosed by visual examination of biopsied liver tissue. Virus-specific molecular assays are typically used to confirm a diagnosis, positively identify the type of hepatitis virus, and determine a course of treatment. Many of the immunological and molecular diagnostic tools discussed in Chapter 29 are used in hepatitis diagnoses. These include enzyme immunoassays that target viral-specific proteins or antiviral antibodies in a blood sample, immunoblots (Western blots), and immunofluorescence (microscopic) methods. Polymerase chain reaction (PCR) tests are also used to detect hepatitis viral genomes in blood or in liver tissue obtained by biopsy.

Infection with HAV or HBV can be prevented with effective vaccines. HBV vaccination is recommended and in most cases is

Figure 31.32 Hepatitis A, B, and C in the United States. In 2016 there were 2007 reported cases of hepatitis A, 3218 reported cases of hepatitis B, and 2967 reported cases of hepatitis C. The number of actual new cases of hepatitis A, B, or C infection is likely to be much higher than the reported new cases. Data obtained from the CDC, Atlanta, Georgia, USA.

(b) Jaundice, a yellowing of the facial skin and eye conjunctiva, is a common symptom of hepatitis infections and results from the accumulation of bilirubin (a by-product of degraded red blood cells) that results from reduced liver function.

required for school-age children in the United States. No effective vaccines are available for the other hepatitis viruses. For those unvaccinated, the practice of *universal precautions* will prevent infection. The precautions prescribe a high level of vigilance and aseptic handling and containment procedures to deal with patients, body fluids, and infected waste materials (◀ Section 29.1). Most treatment of hepatitis is supportive, providing rest and time for the immune system to attack the infection and allow liver damage to be repaired. In some cases, in particular for HBV infections, some antiviral drugs are available that offer effective treatment. Those infected with any of the known strains of hepatitis C virus can be treated with a specific antiviral drug that in most cases effects a complete cure.

31.12 Ebola: A Deadly Threat

A recent example of a highly infectious and deadly serious emerging pathogen that spreads by direct contact is Ebola virus, which ravaged parts of West and central Africa in 2014, 2015, and 2019 (◀ Section 30.7 and Figure 30.10). Ebola has infected over 31,000 people and killed over 12,000 of them.

Ebola emerged in 1976 in Zaire, and since then several small outbreaks have occurred in West African countries. But not until the 2014 outbreak in Guinea, Liberia, Nigeria, Senegal, and Sierra Leone did the disease kill such large numbers of people. However, nearly as fast as the disease reemerged, strong efforts to contain the spread of infection were put in place and these, along with unknown natural events that control cycles of this disease, combined to significantly reduce Ebola incidence. By the end of 2015, only a handful of cases were reported. Ebola reemerged in 2019 in the Democratic Republic of Congo with over 2000 deaths reported. Today, significant epidemiological surveillance for Ebola remains in place because

of the ease of transmission of the virus and thus the rapidity by which a single infection can trigger an outbreak.

Ebola: The Virus and Its Transmission

Ebola hemorrhagic fever is caused by a *filovirus*, a filamentous virus that can take on many shapes (Figure 31.34a). The Ebola virus genome contains single-stranded and linear RNA of the negative sense, similar in this respect to influenza and rabies virus genomes. The genome contains only 19 kilobases of RNA, enough to encode just seven proteins; about a third of the genome encodes the RNA-dependent RNA polymerase (RNA replicase) needed to replicate the genome of negative-sense RNA viruses (◀ Section 11.9).

Ebola virus is transmitted from person to person by direct contact through breaks in the skin or mucous membranes as well as by body fluids (including semen) and fomites (bedding, clothing, utensils) contaminated with the virus. The ease with which Ebola can be transmitted seems remarkable compared with other pathogens that rely on direct-contact transmission. For example, in a few documented instances of Ebola transmission to healthcare workers, significant precautions had been taken to ensure that full-body personal protective equipment (PPE, ▶ Section 29.1) was in place to specifically prevent such transmission. Thus, the disease is not only deadly for those infected but can be an extremely dangerous risk for healthy medical providers as well. If PPE is not worn, healthcare workers who either treat patients or dispose of dead Ebola victims run a high risk of becoming infected. Thus, PPE is routinely worn by international health organization workers who might come in contact with an Ebola patient (Figure 31.34b).

The natural reservoir of Ebola virus that triggered the West African outbreak is unknown, although related filoviruses, such as hantavirus (▶ Section 32.2), are known to be spread from arthropods and rodents. Among the suspected reservoirs of Ebola are a variety of animals and possibly insects that inhabit tropical forests. In addition to person-to-person transmission, likely responsible for virtually all of the cases in the recent West Africa epidemic, natural Ebola infection in humans probably originates from an animal bite. In this regard, bats, and in particular fruit bats in which the virus has been documented, may be a major disease reservoir.

Ebola: The Disease and Its Treatment

Ebola virus migrates from the initial site of infection to lymph nodes, from which it travels systemically to infect the liver and spleen. Once the virus has entered the body, several different types of cells can become infected. One to two weeks postinfection, an Ebola patient experiences an abrupt fever and general malaise, conditions that make Ebola difficult to distinguish from many other tropical diseases, including malaria. But then more severe symptoms appear. These typically include severe fever and fatigue, diarrhea, nausea, vomiting and abdominal pain, and major loss of appetite. Bleeding through the skin and blood in vomit and feces can occur, but such bleeding is not a common symptom.

Ebola virus causes major problems in the liver, killing liver cells and disrupting normal blood clotting events. It is thought that the virus triggers host cells to release various cytokines that cause widespread inflammation (◀ Section 26.8) and internal bleeding; these lead to multiple organ failures, shock, and renal failure. The mortality

rate in the West African Ebola outbreak averaged 35–70% depending on access to treatment, the initial state of health of those infected, viral load (abundance of the virus in the blood), and age; mortality was as high as 85% among infected people over the age of 45.

There is currently no drug treatment for Ebola, but survival rates among those that receive supportive care to help alleviate symptoms are significantly higher than in those that do not. Therapy includes the maintenance of fluids and electrolytes, oxygen supplements, and transfusions of blood to replace that lost from internal bleeding. Ebola survivors develop an antibody-mediated immune response to the virus, and some treatment success has been achieved by transfusing blood or serum from Ebola survivors into those infected. Vaccines for Ebola are in development, and several promising candidates have emerged. Experimental vaccines have been administered with considerable success to healthcare workers in the Democratic Republic of Congo outbreak, and thus it is likely that putting a person's immune system to work against Ebola—through vaccination—will be the best preventive measure against the disease. However, it is unlikely that an Ebola vaccine would help an already infected person, considering the rapidity with which the disease progresses and the major organ damage that viral infection triggers.

Much has been learned from recent Ebola outbreaks concerning the logistics of handling large-scale outbreaks of such a deadly disease. The ease by which Ebola is transmitted made a public education campaign about the dangers of Ebola just as important as dealing with the morbidity and mortality of the outbreak. When epidemiologists develop a better understanding of the natural reservoirs of Ebola virus, outbreaks like that in West Africa—which likely began by animal-to-person transmission—may well be preventable by reducing or eliminating the major reservoirs and educating the populace about the dangers of encounters with known reservoirs. Also, rigorous campaigns to educate people such as family members who put themselves at risk by handling an Ebola patient or the corpse of an Ebola victim without PPE in place are also helping to reduce spread of Ebola when a case or case cluster does appear.

IV • Sexually Transmitted Infections

Diseases spread through sexual contact may be caused by bacteria, viruses, protists, or fungi. Sexually transmitted infections are characterized by latency, persistence, and recurrence, and in some cases are inapparent. Although most sexually transmitted diseases are curable, currently only one type of sexually transmitted infection is preventable by immunization.

Sexually transmitted infections (STIs), also called *sexually transmitted diseases* (STDs), are caused by a wide variety of bacteria, viruses, protists, and even fungi (Table 31.3). Unlike respiratory pathogens that can be shed constantly in large numbers by an infected individual, sexually transmitted pathogens are typically found only in body fluids from the genitourinary tract (and blood, in the case of HIV). Because they require a protected and moist environment, sexually transmitted pathogens preferentially and sometimes exclusively colonize the genitourinary tract.

Because the transmission of STIs is limited to sexual activity, their spread can be controlled by sexual abstinence and minimized by the effective use of condoms that stop the exchange of body fluids during sex. With the exception of HIV/AIDS and genital herpes, most STIs are curable, and many can have only minor symptoms. These realities, combined with the fact that those infected are sometimes reluctant to seek treatment, make treatment of STIs an ongoing

TABLE 31.3 Sexually transmitted infections and treatment guidelines

Disease	Causative organism(s) ^a	Recommended treatment
Gonorrhea	<i>Neisseria gonorrhoeae</i> (B)	Cefixime or ceftriaxone, and azithromycin or doxycycline
Syphilis	<i>Treponema pallidum</i> (B)	Benzathine penicillin G
<i>Chlamydia trachomatis</i> infections	<i>Chlamydia trachomatis</i> (B)	Doxycycline or azithromycin
Nongonococcal urethritis	<i>C. trachomatis</i> (B) or <i>Ureaplasma urealyticum</i> (B) or <i>Mycoplasma genitalium</i> (B) or <i>Trichomonas vaginalis</i> (P)	Azithromycin or doxycycline Metronidazole
Lymphogranuloma venereum	<i>C. trachomatis</i> (B)	Doxycycline
Chancroid	<i>Haemophilus ducreyi</i> (B)	Azithromycin
Genital herpes	Herpes simplex 2 (V)	No known cure; symptoms can be controlled by several antiviral drugs
Genital warts	Human papillomavirus (HPV) (certain strains)	No known cure but preventable by vaccine; symptomatic warts can be removed surgically, chemically, or by cryotherapy
Trichomoniasis	<i>Trichomonas vaginalis</i> (P)	Metronidazole
Acquired immunodeficiency syndrome (AIDS)	Human immunodeficiency virus (HIV)	No known cure; several drugs can stop viral replication and slow disease progression; prophylactic drug available
Pelvic inflammatory disease	<i>N. gonorrhoeae</i> (B) or <i>C. trachomatis</i> (B)	Cefotetan and doxycycline
Vulvovaginal candidiasis	<i>Candida albicans</i> (F)	Butoconazole

^aB, bacterium; V, virus; P, protist; F, fungus.

public health challenge. However, delaying or forgoing treatment of STIs only serves to maintain lines of transmission and can lead to long-term health problems, such as infertility, cancer, heart disease, degenerative nerve disease, birth defects, stillbirth, or destruction of the immune system, any of which can result in death.

31.13 Gonorrhea, Syphilis, and Chlamydia

Gonorrhea, syphilis, and sexually transmitted *Chlamydia* infections are ancient STIs. Whereas the pathogenesis and symptoms of gonorrhea and chlamydial infections are similar in several ways, these STIs are quite different from syphilis. In the United States, cases of gonorrhea and sexually transmitted *Chlamydia* peaked following the introduction of birth control pills in the mid-1960s, and these STIs are still quite prevalent today; cases of syphilis, on the other hand, are less prevalent (Figure 31.35). However, the incidence of all of these STIs has risen significantly in recent years. Between 2013 and 2017

in the United States, reported cases of gonorrhea increased 67%, *Chlamydia* incidence rose by 22%, and diagnoses of syphilis jumped 76% (Figure 31.35).

Gonorrhea

Neisseria gonorrhoeae, often called the gonococcus, causes gonorrhea, a highly prevalent bacterial STI of more than half a million reported cases in the United States in 2017. *N. gonorrhoeae* is a gram-negative and obligately aerobic diplococcus related biochemically and phylogenetically to *Neisseria meningitidis* (Section 31.5). Cells of *N. gonorrhoeae* are killed rapidly by drying, sunlight, and ultraviolet radiation and thus normally do not survive away from the mucous membranes of the pharynx, conjunctiva, rectum, or genitourinary tract (Figure 31.36). Because of this, gonorrhea can be transmitted only by intimate person-to-person contact. We discussed the clinical microbiology and diagnosis of gonorrhea in Section 29.3.

States

Figure 31.35 Reported cases of gonorrhea and syphilis in the United States. Note the downward trend in disease incidence after the introduction of antibiotics and the upward trend in the incidence of gonorrhea after the introduction of birth control pills. In 2017 there were 555,608 new cases of gonorrhea and 30,644 new cases of primary and secondary syphilis in the United States.

Figure 31.36 The causative agent of gonorrhea, *Neisseria gonorrhoeae*. (a) Gram stain of a urethral discharge. (b) Scanning electron micrograph of the microvilli of human fallopian tube mucosa with cells of *N. gonorrhoeae* attached to the surface of epithelial cells. Cells of *N. gonorrhoeae* are about 0.8 μm in diameter. *Neisseria* species are *Betaproteobacteria* (◀ Section 16.2).

The symptoms of gonorrhea are quite different in the male and female. In females, gonorrhea may be asymptomatic or cause a mild vaginitis that is difficult to distinguish from vaginal infections caused by other organisms; hence, the infection may easily go unnoticed. Complications from untreated gonorrhea in females, however, can lead to a chronic condition called *pelvic inflammatory disease* (PID), which can cause severe abdominal pain and sterility. In men, *N. gonorrhoeae* causes an infection of the urethral canal characterized by painful urination (dysuria) and urethral discharge of pus. Complications from untreated gonorrhea affecting both males and females include damage to heart valves and joint tissues due to inflammatory reactions from immune complexes that deposit in these areas. In addition to disease in adults, *N. gonorrhoeae* can also cause eye infections in newborns. Infants born of infected mothers may acquire an eye infection called *ophthalmia neonatorum* from passage through the birth canal. Therefore, prophylactic treatment of the eyes of all newborns with an ointment containing erythromycin is mandatory in much of the United States to prevent gonococcal and other bacterial eye infections in infants.

Treatment of gonorrhea with penicillin was the method of choice until the 1980s when strains of *N. gonorrhoeae* resistant to penicillin emerged. The quinolones ciprofloxacin, ofloxacin, or levofloxacin were also used, but by 2006, a significant fraction of *N. gonorrhoeae* strains isolated in the United States had developed resistance to these drugs as well. Strains resistant to penicillin and quinolones respond to alternative antibiotic therapy with a single dose of the β-lactam antibiotics cefixime or ceftriaxone, especially when given in combination with azithromycin (◀ Figure 28.18).

Despite the fact that drugs are still effective in treating gonorrhea, incidence of gonorrhea remains high (Figure 31.35) for at least three reasons. First, although anti-gonococcal antibodies are generated by an infection, they are strain-specific and provide no protection from

infection by other strains of *N. gonorrhoeae*. As a consequence, gonorrhea reinfection is possible and quite common in high-risk populations (primarily sex workers and those with multiple sex partners). In addition, within a single *N. gonorrhoeae* strain, antigenic switches can thwart the immune response. For example, by mutation *N. gonorrhoeae* can alter the structure of its pilus proteins, thus creating new serotypes to challenge the immune response. Second, oral contraceptives cause a rise in vaginal pH; when this occurs, lactic acid bacteria normally found in the adult vagina fail to develop, and this reduces competition for colonization by *N. gonorrhoeae*. Finally, and most importantly, symptoms of gonorrhea in the female are often so mild that the disease may go unrecognized; a promiscuous infected female can then infect many males.

Syphilis and Yaws

Syphilis is caused by the bacterium *Treponema pallidum* subspecies *pallidum*, a spirochete having a long, thin, and tightly coiled morphology (Figure 31.37). Like *N. gonorrhoeae*, this pathogen is sensitive to environmental stress and drying, and thus syphilis is transmitted only through intimate sexual contact or from mother to fetus during pregnancy (the biology of the spirochetes and the genus *Treponema* is discussed in Section 15.17). A closely related spirochete, *Treponema pallidum* subspecies *pertenue*, causes the tropical disease *yaws* and is more resistant to environmental stressors. Therefore, unlike syphilis, yaws is easily spread by casual (nonsexual) contact through breaks in the skin. Although rarely fatal, about 100,000 new cases of yaws appear every year, mostly in children, producing ulcerous lesions that can be disabling and disfiguring (see Figure 31.39).

Syphilis is often transmitted simultaneously with gonorrhea as a coinfection. However, syphilis is potentially the more serious disease. Despite its lower incidence, syphilis kills nearly 100,000 people per year worldwide, whereas gonorrhea kills fewer than 1000 people

Figure 31.37 The syphilis spirochete, *Treponema pallidum*. (a) Cells from a chancre stained with a fluorescent antibody measure 0.15 μm wide and 10–15 μm long. (b) Silver-stained (Fontana method) preparation of a specimen from a syphilitic chancre. (c) Shadow-cast electron micrograph of a cell of *T. pallidum*. The endoflagella are typical of spirochetes (◀ Section 15.17).

Figure 31.38 Primary and secondary syphilis. (a) Chancres on the lip and (b) the penis in cases of primary syphilis. The chancre is the characteristic lesion of primary syphilis at the site of infection by *Treponema pallidum*. (c) Syphilitic rash on the lower back of a patient showing secondary syphilis.

per year (in some of these cases, the individuals are in poor health to begin with or have coinfections with other pathogens, and so the cause of death may not be due to a single pathogenic agent). Cases of syphilis in the United States have increased dramatically in recent decades, however, with over 30,644 new infections reported in 2017 from a low of around 6000 just ten years earlier. The increase in syphilis incidence may partly be linked to the success of new HIV/AIDS treatments (Section 31.15). Those infected with HIV are often coinfecting with *T. pallidum*, and new anti-retroviral drugs that extend the life span of HIV/AIDS patients allow time for the slowly progressing symptoms of advanced syphilis to appear, thus resulting in diagnosis and case reporting.

Neither subspecies of *T. pallidum* (Figure 31.37) is able to penetrate intact skin, and therefore initial infection takes place through tiny breaks in the epidermis. Initial syphilitic infection is evident with the appearance of a hard lesion called a *chancre*, usually on the penis of males or the vagina, cervix, or perineal region of females. In about 10% of cases, infection is extragenital, usually in the oral region (Figure 31.38a). During pregnancy, the pathogen can be transmitted from an infected woman to the fetus; the disease acquired by the infant is called **congenital syphilis**. For yaws, lesions generally appear on the legs, face, or back where the skin has been broken and direct contact with the spirochete has occurred. The “weeping” lesions of yaws are characterized by a fluid exudate and white, splotchy patches around the perimeter of the ulcer (Figure 31.39).

Stages of Syphilis

Syphilis is a more complex disease than yaws because it progresses through a series of increasingly serious stages. Syphilis always begins with a localized infection called *primary syphilis*, and it is at this stage that *T. pallidum* multiplies at the site of entry and the characteristic hard chancre appears, usually within 2 weeks to 2 months (Figure 31.38a, b). Microscopy of a syphilitic chancre exudate reveals the actively motile spirochetes (Figure 31.37a, b). In most cases, the chancre heals spontaneously, and *T. pallidum* disappears from the site. In untreated cases, however, the highly invasive cells spread

from the initial site to various parts of the body, such as the mucous membranes, eyes, joints, bones, or central nervous system, where extensive multiplication occurs. A hypersensitivity reaction to the invading bacteria often produces the key symptom of *secondary syphilis* at this time—the development of a generalized, often coppery looking skin rash over the whole body (Figure 31.38c).

In the absence of treatment, the subsequent course of the disease varies from case to case. About 25% of infected individuals spontaneously recover and are free of any further disease symptoms. Another one-fourth exhibit no further symptoms but maintain a persistent, chronic syphilitic infection. Roughly half of untreated patients develop *tertiary syphilis*, with symptoms ranging from relatively mild infections of the skin and bone to serious and even fatal infections of the cardiovascular system or central nervous system. This may occur many years after the primary infection. Involvement of the nervous system can cause paralysis or other severe neurological damage (insanity is common in fatal infections). Relatively low

Figure 31.39 Yaws lesion on the face of a young girl caused by *Treponema pallidum* subspecies *pertenue*. The tropical disease yaws, caused by a different subspecies of the same bacterium that causes syphilis, produces splotchy, “weeping” lesions, often with white perimeters. Like syphilis, the debilitating disease can be treated successfully by administering penicillin-based antibiotics.

numbers of *T. pallidum* are present in individuals with tertiary syphilis; most of the symptoms probably result from inflammation due to delayed-type hypersensitivity reactions (◀ Section 28.1) to the pathogen. Tertiary syphilis can still be treated, usually with long-term intravenous antibiotic administration, but prior neurological damage from the syphilitic infection is typically irreversible.

Although several laboratory tests can be used to diagnose *T. pallidum* infections (Chapter 29), the most important physical sign is an ulcerous lesion—either a splotchy, weeping ulcer with yaws or a hard chancre with syphilis. Unlike the case with gonorrhea, penicillin remains highly effective in treating both syphilis and yaws, and both diseases can typically be cured by a single injection of benzathine penicillin G. Oral azithromycin has also been highly effective in treating yaws, often in just a single dose, but some resistance to this antibiotic has emerged among strains of *T. pallidum* that cause syphilis.

Chlamydial Syndromes

A number of sexually transmitted diseases can be ascribed to infection by the obligately intracellular bacterium *Chlamydia trachomatis* (Figure 31.40). This organism is one of a small group of parasitic bacteria that form their own phylum (the *Chlamydiae*) of *Bacteria* (◀ Section 16.15). Because *C. trachomatis* must be grown in host cells (tissue culture), its rapid isolation and identification is not as straightforward as for *Neisseria gonorrhoeae*.

The total incidence of sexually transmitted *C. trachomatis* infections significantly outnumbers the incidence of gonorrhea, making chlamydial infections the most prevalent bacterial STIs in the world. In the United States alone, over 1.7 million chlamydial cases were reported in 2017, nearly half of which were among 15- to 24-year-old females. Because of their often inapparent nature, the actual incidence of sexually transmitted chlamydial infections may be

closer to 4 million cases every year. *C. trachomatis* also causes a serious eye infection called *trachoma*, which is the number one cause of infectious blindness in the world, but the strains of *C. trachomatis* responsible for STIs are usually distinct from those that cause trachoma. Chlamydial infections may also be transmitted congenitally to the newborn in the birth canal, causing newborn conjunctivitis and pneumonia.

Nongonococcal urethritis (NGU) due to *C. trachomatis* is one of the most frequently observed sexually transmitted diseases in males and females, but the infections are often inapparent. In a small percentage of cases, chlamydial NGU leads to serious acute complications, including testicular swelling and prostate inflammation in men and cervicitis, pelvic inflammatory disease, and fallopian tube damage in women. These are due to the ability of *C. trachomatis* to trigger an overblown immune response and inflammation in the host. During NGU, cells of *C. trachomatis* can attach to microvilli of fallopian tube cells, enter, multiply, and eventually lyse the cells (Figure 31.40b). Untreated NGU in a female can thus lead to infertility, ectopic pregnancy, and chronic pelvic pain. Infections with the protist *Trichomonas vaginalis* can cause symptoms similar to those of chlamydial NGU, and we consider trichomoniasis along with other parasitic infections in Chapter 34.

Chlamydial NGU is frequently observed as a secondary infection following gonorrhea. Both *N. gonorrhoeae* and *C. trachomatis* are often transmitted to a new host simultaneously. However, treatment of gonorrhea does not eliminate chlamydial infection. Although cured of gonorrhea, these patients are still infected with *Chlamydia* and eventually experience an apparent recurrence of gonorrhea that is instead a case of chlamydial NGU. Thus, patients treated for gonorrhea with drugs such as cefixime or ceftriaxone are also given azithromycin or doxycycline to treat a potential coinfection with *C. trachomatis*. A variety of clinical techniques including nucleic acid and immunological analyses are available for making a positive diagnosis of *C. trachomatis* infection, but drug therapy in the absence of a positive diagnosis is often prescribed.

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by distinct strains of *C. trachomatis* (referred to as LGV 1, 2, and 3). The disease occurs most frequently in males and is characterized by infection and swelling of the lymph nodes in and about the groin. From the infected lymph nodes, chlamydial cells may travel to the rectum and cause a painful inflammation of rectal tissues called *proctitis*. LGV has the potential to cause regional lymph node damage and the complications of proctitis. It is the only chlamydial infection that invades beyond the epithelial cell layer.

We move on to the final two sections of this chapter to look at sexually transmitted diseases of viral origin.

Figure 31.40 Cells of *Chlamydia trachomatis* (arrows) attached to human fallopian tube tissues. (a) Cells attached to the microvilli of a fallopian tube. (b) A damaged fallopian tube containing a cell of *C. trachomatis* (arrow) in the lesion.

Check Your Understanding

- How are gonorrhea, syphilis, and chlamydial infections diagnosed?
- Explain at least one potential reason for the higher incidence of gonorrhea as compared with syphilis.
- Compare and contrast the symptoms of yaws and syphilis. How are these diseases treated?

31.14 Herpes Simplex Viruses (HSV) and Human Papillomavirus (HPV)

STIs caused by herpesviruses and human papillomaviruses are extremely prevalent among sexually active adults and are often more difficult to diagnose and treat than are bacterial STIs.

Herpes

Herpesviruses are a large group of double-stranded DNA viruses (◀ Section 11.7), many of which are human pathogens. The herpes simplex viruses are responsible for both cold sores and genital infections.

Herpes simplex 1 virus (HSV-1) infects the epithelial cells around the mouth and lips, causing cold sores (also called fever blisters) that occasionally spread to other parts of the face in severe infections (Figure 31.41). HSV-1 is spread via direct contact with infectious lesions or through saliva. The incubation period of HSV-1 infections is short (3–5 days), and the lesions heal without treatment in 2–3 weeks. However, latent herpes infections are common, because the virus typically persists in low numbers in nerve ganglia. Recurrent acute herpes infections can then occur when the virus is triggered by coinfections with other pathogens or by bodily stress. Oral herpes caused by HSV-1 is quite common and apparently has no long-term harmful effects on the host, beyond the discomfort of the oral blisters.

Herpes simplex 2 virus (HSV-2) infections are associated primarily with the anogenital region, where the virus causes painful blisters on the penis of males or on the cervix, vulva, or vagina of females (Figure 31.42). HSV-2 infections are generally transmitted by direct sexual contact, and the disease is most easily transmitted when active blisters are present but may also be transmitted during asymptomatic periods, even when the infection is presumably latent. HSV-2 occasionally infects other sites such as the mucous membranes of the mouth and can also be transmitted to a newborn by contact with herpetic lesions in the birth canal at birth. The disease in the newborn varies from latent infections with no apparent damage to systemic disease resulting in brain damage or even death. To avoid herpes infections in newborns, delivery by cesarean section is advised for pregnant women with genital herpes infections.

The long-term effects of genital herpes infections are not fully understood. However, studies have indicated a significant correlation between genital herpes infections and cervical cancer in females. Genital herpes infections are presently incurable, although a limited

Figure 31.41 Herpes simplex 1 virus infections. (a) A severe case of herpes blisters on the face due to infection with herpes simplex 1 virus. (b) Close-up view of herpes blisters by the eye.

Figure 31.42 Herpes simplex 2 virus infections. Herpes simplex 2 virus blisters on the (a) penis and (b) vulva. As for herpes type 1, acute type 2 herpes infections can seemingly be cured only to reappear later from a persistent virus infection (◀ Section 5.7).

number of drugs have been successful in controlling the infectious blister stages. The guanine analog acyclovir (Figure 31.43), given orally and also applied topically, is particularly effective in limiting the shed of active virus (both HSV-1 and HSV-2) from blisters and promoting the healing of blistering lesions (Figures 31.41 and 31.42). Acyclovir, and the related drugs valacyclovir and vidarabine, are nucleoside analogs that interfere with herpesvirus DNA replication, thus inhibiting viral multiplication.

Human Papillomavirus

As for herpesviruses, **human papillomaviruses (HPV)** comprise a family of double-stranded DNA viruses. Of more than 100 different strains, about 30 are transmitted sexually, and several of these cause genital warts and cervical cancer. Up to 80% of women aged over 50 have had at least one HPV infection. There are 14 strains of HPV that cause cervical cancer. HPV types 16 and 18 cause 70% of cervical cancers and pre-cancerous cervical lesions. Cervical cancer is the fourth most common cancer among women globally, with an estimated 570,000 new cases in 2018, resulting in 311,000 fatalities.

Most HPV infections are asymptomatic, with some progressing to cause genital warts. Others cause cervical neoplasia (abnormalities in cells of the cervix), and a few progress to cervical cancers. Most HPV infections resolve spontaneously but, as with many viral infections, there is no adequate treatment or cure for active infections. Because human papillomaviruses are potentially oncogenic (cancer-causing), available HPV vaccines, such as the widely used HPV

Figure 31.43 Guanine and the guanine analog acyclovir. Acyclovir has been used therapeutically to control genital herpes (HSV-2) blisters (Figure 31.42).

9-valent vaccine (marketed as Gardasil®), are currently recommended for use in females 11–26 years of age. The HPV vaccine is also recommended for males to prevent anal and penile cancers and also because immunized males do not carry HPV and thus cannot infect females. In addition, the HPV vaccine should reduce incidence of certain neck and throat cancers in both males and females caused by the same sexually transmitted strains of HPV.

Check Your Understanding

- Describe pertinent clinical features and treatment protocols for herpes simplex viruses and human papillomaviruses.
- Why are these diseases more difficult to diagnose than gonorrhea or syphilis?

31.15 Human Immunodeficiency Virus (HIV) and AIDS

Acquired immunodeficiency syndrome (AIDS) is caused by the human immunodeficiency virus (HIV). Worldwide, nearly 80 million people have been infected with HIV, with an estimated 6000 more added each day, and over 35 million have died. In the United States, from a total of 5 cases diagnosed in 1981, over 1.1 million people are infected with HIV today. We covered some aspects of the epidemiology of HIV/AIDS in Section 30.8 and will pick up on that theme here.

HIV and a Definition of AIDS

HIV is of two types, *HIV-1* and *HIV-2*, but because more than 99% of global AIDS cases are due to HIV-1, we focus on HIV-1 here. HIV-1 is a retrovirus (◀ Sections 5.7 and 11.11) that replicates in macrophages and T cells of the human immune system (Chapters 26 and 27). HIV infection eventually leads to the destruction of key immune system cells, virtually eliminating the host immune response. Death from AIDS is usually the result of a secondary infection, typically one caused by an **opportunistic pathogen**,

pathogens that in a healthy individual would be controlled by the immune system.

The current definition of a case of HIV/AIDS is a patient who tests positive for HIV in immunological and/or nucleic acid–based tests and meets at least one of the following two criteria:

1. A CD4 T cell number of less than 200/ μl of whole blood (the normal count is 600–1000/ μl) or a CD4 T cell/total lymphocytes percentage of less than 14%.
2. A CD4 T cell number of more than 200/ μl and any of the following diseases: candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, cystoisosporiasis, *Pneumocystis jirovecii* pneumonia, cryptosporidiosis, or toxoplasmosis of the brain (all fungal or protozoal diseases, Chapter 34); pulmonary tuberculosis or other mycobacterial infections, or recurrent *Salmonella* septicemia (bacterial diseases); cytomegalovirus infection, HIV-related encephalopathy, HIV wasting syndrome, chronic ulcers, or bronchitis due to herpes simplex (viral infections); or certain malignant diseases such as invasive cervical cancer, Kaposi's sarcoma, Burkitt's lymphoma, primary lymphoma of the brain, or immunoblastic lymphoma; or recurrent pneumonia due to any agent.

Pathogenesis of HIV/AIDS

HIV infects cells that have the CD4 cell surface protein. The two cell types most commonly infected are macrophages and T-helper (Th) lymphocytes, both of which are important components of the immune system. Infection normally occurs first in macrophages. At the macrophage cell surface, the CD4 molecule binds to the gp120/gp41 capsid protein of HIV as the virus interacts with the macrophage receptor CCR5 (Figure 31.44). CCR5 is a coreceptor for HIV and, together with CD4, forms the docking site where the HIV envelope fuses with the host cytoplasmic membrane; this is required for the viral nucleocapsid to be inserted into the cell (Figure 31.44b). Within the macrophage, HIV replicates and makes an

with HIV

Figure 31.44 Infection of a CD4 target cell with HIV. (a) Recognition and binding of HIV by CCR5 and CD4 receptors. (b) The viral nucleocapsid eventually enters the cell. Details of the replication of the HIV genome were shown in Figure 11.27.

Figure 31.45 **Decline of CD4 T lymphocytes and progress of HIV infection.** During the typical progression of untreated AIDS, there is a gradual loss in the number and functional ability of the CD4 T cells, while the viral load, measured as HIV-specific RNA copies per milliliter of blood, gradually increases after an initial decline.

altered form of gp120 that recognizes a different coreceptor, CXCR4, on Th cells. HIV virions are released from macrophages and proceed to infect and replicate in Th lymphocytes. Infected Th cells that produce HIV no longer divide and are eventually diminished by attrition.

In some HIV/AIDS patients, HIV infection does not progress immediately to killing host immune cells. HIV can exist in a dormant state as a provirus; under these conditions, the reverse-transcribed HIV genome, now in the form of DNA, is integrated into host chromosomal DNA (◀ Figure 11.27). At this point the cell may show no outward sign of infection. Indeed, HIV DNA can remain latent for long periods, replicating only as the host cell DNA replicates. However, sooner or later, HIV begins to replicate, and progeny viruses are produced and released from the cell.

Symptoms of HIV/AIDS

Ongoing HIV infection results in a progressive decline in CD4 cell numbers. In a healthy human, CD4 cells constitute about 70% of the total T cell pool. In those with HIV/AIDS, CD4 numbers steadily decrease, and by the time opportunistic infections begin to appear, CD4 cells are all but absent (Figure 31.45). The progression of untreated HIV infection to AIDS follows a typical pattern. First, there is an intense immune response to HIV, and HIV numbers drop. But eventually, the immune response is overwhelmed, and HIV levels slowly increase while CD4 T cells slowly decrease. When T cell numbers have dropped below about 200/mm³ of blood, infections by opportunistic pathogens can occur (Figure 31.45).

Opportunistic infections caused by normally controllable protists, fungi, bacteria, and viruses occur with high prevalence in those with HIV/AIDS and are typically the actual cause of death (Figure 31.46). The most common opportunistic disease in HIV/AIDS patients is pneumonia caused by the fungus *Pneumocystis jirovecii* (Figure 31.46d), but infections by various molds, yeasts, protists, and bacteria are also seen (Figure 31.46). Bacterial infections are less

common than those of eukaryotic pathogens, but when they occur, they are frequently of strongly antibiotic-resistant bacteria, such as multiple-drug-resistant *Mycobacterium tuberculosis*.

Eukaryotic opportunistic pathogens are difficult to treat in general because many of the drugs used to treat infections from fungi and protists have significant negative side effects on the host, which of course is also a eukaryote. A cancer frequently seen in HIV/AIDS patients is *Kaposi's sarcoma*, a cancer of the cells lining the blood vessels and characterized by purple splotches on the skin, especially in the extremities (Figure 31.47). Kaposi's sarcoma is caused by coinfection of HIV and human herpesvirus 8 (HHV-8) and is rarely seen outside of HIV/AIDS patients.

Diagnosing HIV/AIDS

HIV infection is typically diagnosed by identifying antibodies to the pathogen in a patient blood sample. An enzyme immunoassay (EIA, ◀ Figure 29.20) is used for HIV screening purposes, typically for screening done on a large scale, such as with donated blood. A positive HIV EIA must be confirmed by an HIV immunoblot (Western blot, ◀ Figure 29.22) or by immunofluorescence (◀ Section 29.6) to rule out the possibility of a false-positive screening test. Rapid and inexpensive HIV tests are also available for preliminary screening of blood in clinics. One test requires only a single drop of patient blood and detects the gp41 HIV surface antigen (Figure 31.44) by producing a visible agglutination reaction. A second uses saliva as a source of anti-HIV antibodies and yields a colored product. In general, however, these rapid tests are not as sensitive or specific as the standard HIV EIA and thus positive tests should be confirmed by more sensitive and specific tests. Unfortunately, no matter how sensitive or specific, none of the antibody tests will detect those who have recently acquired the virus and are infectious but have not yet made a detectable antibody response to HIV, which may require a period of 6 weeks or more following infection.

Figure 31.46 Opportunistic pathogens associated with HIV/AIDS. (a) *Candida albicans*, from heart tissue of patient with systemic *Candida* infection. (b) *Cryptococcus neoformans*, from lung tissue of an AIDS patient. (c) *Histoplasma capsulatum*, showing reproductive structures called macroconidia. (d) *Pneumocystis jirovecii*, from lungs of an immune-compromised patient. (e) *Cryptosporidium* sp. from small intestine of a patient with cryptosporidiosis. (f) *Toxoplasma gondii*, from heart tissue of patient with toxoplasmosis. (g) *Mycobacterium* spp. infection of the small bowel (acid-fast stain). *Candida*, *Cryptococcus*, *Histoplasma* and *Pneumocystis* are fungi; *Cryptosporidium* and *Toxoplasma* are protists; *Mycobacterium* is a species of *Bacteria*. Coverage of many of these fungal and parasitic diseases can be found in Chapter 34.

Diagnostic procedures also are available that directly measure the number of HIV virions in a blood sample. These tests use a virus-specific reverse transcription–polymerase chain reaction assay (RT-PCR, ◀ Sections 12.1 and 29.8). RT-PCR estimates the number of HIV virions present in the blood, called the **viral load** (Figure 31.48). The RT-PCR test for HIV load is not routinely used to screen for HIV because it is costly and technically demanding. However, after an initial diagnosis, the test is often used to monitor progression of an HIV infection (Figure 31.48) and the effectiveness of chemotherapy.

Treatment of HIV/AIDS

The prognosis for an *untreated* HIV-infected individual is poor, as opportunistic pathogens or malignancies (Figures 31.46 and 31.47) eventually kill virtually all infected persons. Long-term studies indicate that the average person infected with HIV progresses through several stages of decreasing immune function, with CD4 cells dropping from a normal range of 600–1000/mm³ of blood to near zero over a period of 5–7 years (Figure 31.45). Although the rate of decline varies from one HIV-infected individual to another, it is rare for an HIV-positive individual to live for more than 10 years without anti-HIV drug therapy (see MicrobiologyNow in the Chapter 27 opener for exceptions).

Several drugs have been developed that delay the progression of HIV/AIDS and significantly prolong the life of those infected with

HIV. Therapy is aimed at reducing the viral load of HIV-infected individuals to below detectable levels. The strategy to accomplish this is called *highly active anti-retroviral therapy* (HAART) and is carried out by administering at least three anti-retroviral drugs at once to inhibit the replication of HIV and prevent the development of drug-resistant strains. Multiple drug therapy, however, is not a cure for HIV infection. In individuals who have no detectable viral load after drug treatment, a significant viral load returns if therapy is interrupted or discontinued, or if multiple drug resistance develops.

Effective anti-HIV drugs fall into four categories, including two classes of *reverse transcriptase inhibitors*, various *protease inhibitors*, *fusion inhibitors*, and *integrase inhibitors*. Reverse transcriptase is the enzyme that converts the single-stranded RNA genome of HIV into cDNA and then double-stranded DNA and is essential for viral replication (◀ Sections 5.7 and 11.11). Cells lack reverse transcriptase, and thus reverse transcriptase inhibitors are virus-specific. *Azidothymidine* (AZT), also called zidovudine, closely resembles the nucleoside thymidine but lacks the correct attachment site for the next base in a replicating nucleotide chain, resulting in termination of the growing DNA chain. AZT is thus a **nucleoside reverse transcriptase inhibitor** (Figure 31.49a). **Nonnucleoside reverse transcriptase inhibitors**, such as *nevirapine* (Figure 31.49b), inhibit the activity of reverse transcriptase in a different way by interacting with the protein and altering the conformation of the catalytic site.

Figure 31.47 Kaposi's sarcoma. Lesions are shown as they appear on (a) the heel and lateral foot, and (b) the distal leg and ankle.

Other anti-HIV drugs include the **protease inhibitors**, such as *saquinavir* (◀ Figure 28.20b). These are peptide analogs that bind to the active site of the processing enzyme, *HIV protease*, thus inhibiting the processing required to activate retroviral polypeptides; this effectively inhibits viral maturation. **Fusion inhibitors** include *enfuvirtide*, a synthetic peptide that functions by binding to the gp41 protein on HIV capsids (Figure 31.44); this stops fusion of the viral envelope and the CD4 cell cytoplasmic membrane. Finally, there are the **integrase inhibitors**, such as *elvitegravir* and *raltegravir*. These drugs target HIV integrase, the protein that integrates the HIV genome into host cell DNA. The interference with integration of viral DNA into the host cell genome interrupts the HIV replication cycle.

All anti-HIV drugs rapidly decrease the viral load when given to HIV-infected individuals, but drug-resistant strains of HIV arise quickly if only a single drug is administered. A typical HAART protocol for treatment of an established HIV infection includes at least one protease or nonnucleoside reverse transcriptase inhibitor plus a combination of two nucleoside reverse transcriptase inhibitors. A resistant virus would, therefore, have to develop resistance to three drugs simultaneously, an unlikely event. A patient receiving this combination therapy is then monitored to track changes in viral load (Figures 31.45 and 31.48). An effective HAART protocol reduces viral load to nondetectable levels within several days. Drug therapy is then continued and the patient monitored for viral load indefinitely. If the viral load again reaches detectable limits, the drug cocktail is changed because an increase in viral load indicates the emergence of drug-resistant HIV.

In addition to drug resistance, some HAART protocols must be modified because of host toxicity. In many cases, nucleoside analogs are not well tolerated by patients, presumably because they interfere with host functions such as cell division. In general, the nonnucleoside reverse transcriptase inhibitors and the protease inhibitors are better tolerated because they target virus-specific functions. However, drug resistance and host toxicity are major problems in all

forms of HIV therapy. Thus, new chemotherapeutic agents and drug protocols are constantly being developed and tailored to the needs of individual patients.

HIV/AIDS Prevention

Although a number of experimental vaccines are in development, several of which are currently undergoing clinical trials, no HIV vaccine has been approved for clinical use. Public education about how HIV/AIDS is transmitted, sexual abstinence, and avoidance of high-risk behavior remain the best strategies to prevent HIV/AIDS. HIV spread is linked to promiscuous sexual activities and other activities that involve exchange of body fluids, which include not only men who have sex with men, but also prostitution and intravenous drug use where needles are shared. In some countries, the fastest growing mode of HIV transmission is actually between promiscuous heterosexual partners. Effective prevention of HIV transmission therefore

Figure 31.48 Monitoring of HIV load. (a) Procedure for detecting HIV by reverse transcription–polymerase chain reaction (RT-PCR) techniques. (b) Time course for HIV infection as monitored by HIV load and CD4 T cell counts. In the upper panel, a viral load greater than 10⁴ copies/ml correlates with below normal CD4 cell numbers (normal = 600–1000/mm³), indicating a poor prognosis and early death of the patient. In the lower panel, a viral load less than 10⁴ copies/ml correlates with normal CD4 cell numbers, indicating a good prognosis and extended survival of the patient. Data are adapted from the CDC, Atlanta, Georgia, USA.

Figure 31.49 HIV/AIDS chemotherapeutic drugs. (a) Azidothymidine (AZT), also called zidovudine, a nucleoside reverse transcriptase inhibitor. This nucleoside analog is missing the –OH group on the 3'-carbon, causing nucleotide chain elongation to terminate when the analog is incorporated, inhibiting virus replication. (b) Nevirapine, a nonnucleoside reverse transcriptase inhibitor, binds directly to the catalytic site of HIV reverse transcriptase, also inhibiting elongation of the nucleotide chain.

requires avoiding these high-risk behaviors, using condoms whenever the health of a sex partner is in doubt, and, for anyone who has engaged in high-risk behavior, undergoing an HIV blood test.

Check Your Understanding

- Review the definition of HIV/AIDS. Which symptoms of HIV/AIDS are shared by all HIV/AIDS patients?
- What does the enzyme reverse transcriptase do, and why is it a good target for anti-HIV drugs?
- What is HAART therapy for treating AIDS patients?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Airborne Bacterial Diseases

- 31.1** Bacterial and viral respiratory pathogens are transmitted in air. Most respiratory pathogens are transferred from person to person via respiratory aerosols generated by coughing, sneezing, talking, or breathing, or by direct or fomite contact. Respiratory pathogens infect either the upper or lower respiratory tracts and sometimes both.

Q What enables *Staphylococcus* and *Mycobacterium* to survive drying and persist in dust for long periods?

- 31.2** Streptococcal diseases include strep throat and pneumococcal pneumonia. *Streptococcus pyogenes* infections may progress into serious conditions such as scarlet and rheumatic fevers, and pneumococcal pneumonia can have high mortality. Both pathogens can be cultured, and both are treatable with antimicrobial drugs, including penicillin.

Q Describe one method to diagnose strep throat quickly. Why may this method be better than a throat culture?

- 31.3** Diphtheria is an acute respiratory disease caused by *Corynebacterium diphtheriae*. Early childhood immunization is effective for preventing this very serious respiratory disease. Whooping cough is an endemic disease caused by *Bordetella pertussis*. Immunization of children, adolescents, and adults can control its propagation and spread.

Q What causes a strain of *C. diphtheriae* to be pathogenic? Describe how such a strain may cause death in an infected patient?

- 31.4** Tuberculosis is one of the most prevalent and dangerous infectious diseases in the world. Its incidence is increasing in developed countries in part because of the emergence of drug-resistant strains of *Mycobacterium tuberculosis*. The pathology of tuberculosis and other mycobacterial

syndromes such as Hansen's disease (leprosy) is influenced by the cell-mediated immune response.

Q Describe the process of infection by *Mycobacterium tuberculosis*. Does infection always lead to active tuberculosis? Why or why not? How is exposure to *M. tuberculosis* detected in humans?

- 31.5** *Neisseria meningitidis* is a common cause of meningococemia and meningitis in young adults and occasionally occurs in epidemics in enclosed populations. Bacterial meningitis and meningococemia can have high mortality rates, and treatment and prevention strategies including vaccines are available.

Q How is *Neisseria meningitidis* typically transmitted, and what are the symptoms of full-blown meningitis caused by this bacterium?

II • Airborne Viral Diseases

- 31.6** Viral respiratory diseases are highly infectious and may cause serious health problems, although most are controllable and not life-threatening. The measles/mumps/rubella (MMR) vaccine is highly effective in controlling these diseases.

Q Compare and contrast measles, mumps, and rubella. Include a description of the pathogen, major symptoms encountered, and any potential consequences of these infections. Why is it important that women be vaccinated against rubella before puberty?

- 31.7** Colds are the most common infectious viral diseases. Usually caused by a rhinovirus, colds are generally mild and self-limiting diseases; over-the-counter "cold drugs" may help to moderate symptoms but are not a cure. Each infection induces specific, protective immunity, but the large

number of cold viruses precludes complete protective immunity or vaccines.

Q Why are colds such common respiratory diseases, and why are vaccines not used to prevent colds?

- 31.8** Influenza is caused by an RNA virus that contains a segmented genome and is easily transmitted by the airborne route. Influenza outbreaks occur annually as a result of the plasticity of the influenza genome. Antigenic drift varies the nature of the viral envelope of influenza viruses in minor ways, causing influenza seasonal epidemics, while antigenic shift varies the virus in major ways and can trigger periodic influenza pandemics. Surveillance and immunization are used to control influenza.

Q Why is influenza such a common respiratory disease? How are annual influenza vaccines developed?

III • Direct-Contact Bacterial and Viral Diseases

- 31.9** Staphylococci are usually benign inhabitants of the upper respiratory tract and skin, but several serious diseases can result from pyogenic infection or from the activity of staphylococcal superantigen exotoxins. Antibiotic resistance is common, even in community-acquired infections. MRSA strains of *Staphylococcus aureus* can be very difficult to treat and cause significant tissue damage.

Q Distinguish between pathogenic staphylococci and those that are part of the normal microbiota.

- 31.10** *Helicobacter pylori* infection is the common cause of gastric ulcers. As an infectious disease, gastric ulcers are best treated with antibiotics to promote a permanent cure.

Q Describe the evidence linking *Helicobacter pylori* to gastric ulcers. How can these ulcers be cured?

- 31.11** Viral hepatitis can result in acute liver disease, which may be followed by chronic liver disease (cirrhosis). Hepatitis B and C viruses in particular are transmitted by direct contact and can cause chronic infections leading to liver cancer. Vaccines are available for hepatitis viruses A and B. Viral hepatitis is still a major public health problem because of the high infectivity of the viruses and the lack of effective treatments.

Q Describe the major hepatitis viruses. How are they related to one another? How is each spread?

- 31.12** Ebola hemorrhagic fever is a deadly viral disease spread by direct contact through the skin or from contaminated body fluids. Mortality rates from Ebola are near the highest of all diseases. Treatment is primarily supportive of symptoms, but vaccine trials have shown that effective vaccination protocols are possible.

Q The Ebola virus cannot depend on the host to synthesize its genome; why not?

IV • Sexually Transmitted Infections

- 31.13** Gonorrhea, syphilis, and chlamydial infections caused by *Neisseria gonorrhoeae*, *Treponema pallidum*, and *Chlamydia trachomatis*, respectively, are sexually transmitted infections (STIs) with potential serious consequences if infections are not treated. In the United States, the incidence of all three of these STIs has increased in recent years, with chlamydial infections being the most prevalent of bacterial STIs. The tropical disease yaws is not an STI but is caused by a subspecies of *Treponema pallidum* closely related to the syphilitic spirochete.

Q Why did the incidence of gonorrhea rise dramatically in the mid-1960s, while the incidence of syphilis actually decreased at the same time?

- 31.14** Herpes simplex viruses cause incurable infections transmitted by oral or genital contact with herpes simplex 1 or herpes simplex 2, respectively. Human papillomaviruses cause widespread STIs that may lead to cervical and other cancers, but effective HPV vaccines are available.

Q Describe the viruses that cause genital herpes and genital warts. In each case, is a preventive vaccine available? Is treatment of these STIs possible, and if so, is it an effective cure? Why or why not?

- 31.15** HIV is a retrovirus that destroys the immune system, leading to AIDS, and opportunistic pathogens eventually kill the host. There is no effective cure or vaccine for HIV infection, although antiviral drugs may slow or stop the progress of AIDS. Preventing HIV infection requires education and avoidance of high-risk behaviors involving exchange of body fluids.

Q Describe how human immunodeficiency virus (HIV) effectively shuts down both antibody-mediated and cell-mediated immunity. What is HAART therapy?

APPLICATION QUESTIONS

1. Why is it that you get a cold or two each year but if you have had a case of measles, it was a one-time occurrence?
2. Your college roommate goes home for the weekend, becomes extremely ill, and is diagnosed with bacterial meningitis at a local hospital. Because he was away, university officials are not aware of his illness. What should you do to protect yourself against meningitis? Should you notify university health officials?
3. Contrast an HIV infection with an infection by any other viral pathogen considered in this chapter, regardless of mode of transmission. Why do untreated cases of HIV infection almost always lead to death whereas untreated cases of chicken pox, influenza, or even hepatitis typically do not?
4. Discuss how the quarantines and lockdowns occurring throughout the world due to the spread of SARS-CoV-2 may impact the incidence of influenza globally. How do you think these public health precautions will affect the transmission of other airborne diseases such as measles? (Hint: you may want to look to these resources: (1) <https://www.nature.com/articles/d41586-020-01011-6> and (2) <https://www2.health.vic.gov.au/about/publications/researchandreports/seasonal-influenza-reports-2020>)

CHAPTER GLOSSARY

Antigenic drift a minor change in influenza virus antigens due to gene mutation

Antigenic shift a major change in influenza virus antigen due to gene reassortment between different strains

Cirrhosis breakdown of normal liver architecture, resulting in fibrosis and compromised liver function

Congenital syphilis syphilis contracted by an infant from its mother during pregnancy

Fusion inhibitor a synthetic polypeptide that binds to viral glycoproteins, inhibiting fusion of viral and host cell membranes

Hepatitis liver inflammation, commonly caused by an infectious agent

Human papillomavirus (HPV) a sexually transmitted virus that causes genital warts, cervical neoplasia, and cancer

Integrase inhibitor a drug that interrupts the HIV replication cycle by interfering with integrase, the HIV protein that catalyzes the integration of viral dsDNA into host cell DNA

Meningitis inflammation of the meninges (brain tissue), sometimes caused by *Neisseria meningitidis* and characterized by sudden onset of headache, vomiting, and stiff neck, often progressing to coma within hours

Meningococemia a rapidly progressing severe disease caused by *Neisseria meningitidis* and characterized by septicemia, intravascular coagulation, and shock

Nonnucleoside reverse transcriptase inhibitor a nonnucleoside compound that inhibits the action of retroviral reverse transcriptase by binding directly to the catalytic site

Nucleoside reverse transcriptase inhibitor a nucleoside analog compound that inhibits the action of retroviral reverse transcriptase by competing with nucleosides

Opportunistic pathogen an organism that causes disease only in the absence of normal host resistance

Pertussis (whooping cough) a disease caused by a respiratory tract infection with

Bordetella pertussis, characterized by a deep, persistent cough

Protease inhibitor a compound that inhibits the action of viral protease by binding directly to the catalytic site, preventing viral protein processing

Rheumatic fever an inflammatory autoimmune disease triggered by an immune response to infection by *Streptococcus pyogenes*

Scarlet fever the characteristic reddish rash with fever and sore throat resulting from an exotoxin produced by *Streptococcus pyogenes*

Sexually transmitted infection (STI) an infection that is usually transmitted by sexual contact

Toxic shock syndrome (TSS) the acute systemic shock resulting from a host response to an exotoxin produced by *Staphylococcus aureus*

Tuberculin test a skin test for previous infection with *Mycobacterium tuberculosis*

Viral load a quantitative assessment of the amount of virus in a host organism, usually in the blood

The Historical Emergence of an Ancient and Deadly Pathogen

Although a handful of other diseases throughout history have claimed more human lives—namely smallpox, measles, and perhaps influenza—no other infectious disease has elicited more fear and dread than *plague*.

Causing an estimated 75 million deaths, the “Black Death,” as it came to be called during devastating European outbreaks in the 14th century, is indeed a prolific killer. As described in this chapter, plague is accompanied by a particularly grim suite of symptoms caused by the gram-negative bacterium *Yersinia pestis* (photo, cells of *Y. pestis* [yellow] embedded in a stringy matrix on spines [purple] that line the digestive tract of the rat flea, the vector for this pathogen). As the name *Y. pestis* implies, plague is a classic example of a pestilence that can quickly attain epidemic proportions, and often has. But what triggers the emergence of deadly pathogens like *Y. pestis*?

Recent evidence suggests that, under certain conditions, highly virulent pathogens can emerge over a relatively short period of time. In the case of plague, this emergence was closely linked to the appearance of large Eurasian farming

settlements of up to 20,000 inhabitants about 6000 years ago. By combining archaeological evidence with molecular analyses of DNA extracted from ancient human remains, researchers investigating the decline of Neolithic European populations discovered that multiple lineages of *Y. pestis*—some now extinct—may have been largely responsible, triggering epidemics more ancient than any previously known. Newly established trade routes (made possible by large-animal domestication, metallurgy, and wheeled transport) connecting densely populated, unsanitary habitations likely created favorable conditions for the transmission of *Y. pestis*, resulting in the sudden collapse of many of the earliest agricultural settlements in Europe.

Studies of this nature reveal just how quickly pathogens can emerge and shape human activities, as observed in recent years with the Ebola and Zika viruses.

Source: Rascovan, N., et al. 2018. Emergence and spread of basal lineages of *Yersinia pestis* during the Neolithic decline. *Cell* 176: 1. doi:10.1016/j.cell.2018.11.005.

In this chapter we focus on pathogenic bacteria and viruses transmitted to humans by animals, arthropods, or soil. Animal-transmitted pathogens have their origins in nonhuman vertebrates, and these infected animal populations can transmit infections to humans. Some arthropods are disease vectors, spreading pathogens to new hosts from a bite. Soilborne pathogens are transmitted to humans through either direct contact with soil or contact with contaminated animal fur or hides. A few of the diseases we will explore in this chapter produce only mild symptoms and are typically self-limiting, but most are highly dangerous with life-threatening symptoms and high mortality rates. These include such dreaded diseases as rabies, hantavirus syndromes, yellow fever, and plague.

Table 32.1 summarizes several of the vectorborne and soilborne diseases we will encounter in this chapter and includes the pathogen responsible for each and its mode of transmission.

TABLE 32.1 Viral and bacterial pathogens of selected vector- and soilborne diseases		
Disease	Pathogen	Mode of transmission
Viral diseases		
Rabies	Rabies virus (<i>Rhabdoviridae</i>)	Infected mammal bite
Hantavirus pulmo- nary syndrome	Hantavirus (<i>Hantaviridae</i>)	Rodent excreta inhala- tion/ingestion
Lassa fever	Lassa virus (<i>Arenaviridae</i>)	Rodent excreta inhala- tion/ingestion
Oropouche fever	Oropouche virus (<i>Peribunyaviridae</i>)	<i>Culicoides</i> biting midge
Yellow fever	Yellow fever virus (<i>Flaviviridae</i>)	<i>Aedes aegypti</i> mosquito
Dengue fever	Dengue virus (<i>Flaviviridae</i>)	<i>Aedes aegypti</i> mosquito
Zika virus disease	Zika virus (<i>Flaviviridae</i>)	<i>Aedes aegypti</i> mosquito
Chikungunya disease	Chikungunya virus (<i>Togaviridae</i>)	<i>Aedes aegypti</i> mosquito
West Nile fever	West Nile virus (<i>Flaviviridae</i>)	<i>Culex quinquefasciatus</i> mosquito
Bacterial diseases		
Typhus	<i>Rickettsia prowazekii</i>	Body or head louse
Spotted fever rickettsiosis	<i>Rickettsia rickettsii</i>	Dog or wood tick
Ehrlichiosis	<i>Ehrlichia chaffeensis</i>	Ticks (various)
Q fever	<i>Coxiella burnetii</i>	Contact with infected animals
Lyme disease	<i>Borrelia burgdorferi</i>	Deer tick
Plague	<i>Yersinia pestis</i>	Rat flea
Anthrax	<i>Bacillus anthracis</i> ^a	Inhalation/ingestion/ broken skin
Tetanus	<i>Clostridium tetani</i> ^a	Deep puncture wound
Gas gangrene	<i>Clostridium perfringens</i> ^a	Injury causing tissue ischemia

^aTransmission of these species is typically via endospores found in soil or on soil-contaminated surfaces; in the case of anthrax, inhalation of airborne endospores may occur, leading to pulmonary disease (◀ Section 30.9).

I • Animal-Transmitted Viral Diseases

Although not as prevalent as arthropod-borne viruses, animal-transmitted viruses, including rabies virus and hantavirus, are some of the most lethal pathogens known. Despite vaccines of high efficacy for use in both animals and humans, rabies alone kills tens of thousands of people every year worldwide.

Some diseases are transmitted from animals to humans. A **zoonosis** is an animal disease transmissible to humans, generally by direct contact, aerosols, or bites (Table 32.1). Immunization and veterinary care can control many infectious diseases in domesticated animals, reducing the transfer of zoonotic pathogens to humans. However, wild animals neither receive veterinary care nor are they immunized, making them a source of potential zoonoses. Diseases in animals may be **enzootic**, present endemically in certain populations, or **epizootic**, with incidence reaching epidemic proportions. In the first part of the chapter we focus on two typically enzootic viral diseases, rabies and hantavirus syndromes, both of which can be transmitted to humans.

32.1 Rabies Virus and Rabies

Rabies occurs in wild animals, and the major enzootic reservoirs of rabies virus in the United States are raccoons, skunks, coyotes, foxes, and bats. A small number of rabies cases also occur annually in domestic animals (Figure 32.1).

Symptoms and Pathology of Rabies

Rabies is caused by a rhabdovirus, a single-stranded minus-sense RNA virus (◀ Section 11.9) that infects cells of the central nervous system in most endothermic (warm-blooded) animals, almost invariably leading to death once symptoms have developed. The virus (Figure 32.2a) enters the body from virus-contaminated saliva through a wound from a bite or through contamination of mucous membranes. Rabies virus multiplies at the site of inoculation and travels to the central nervous system. The incubation period before the onset of symptoms is highly variable and depends on the host; the size, location, and depth of the inoculating wound; and the titer of rabies virions transmitted in the bite. In dogs, the incubation period for rabies is less than 2 weeks. By contrast, in humans, 9 months or more may pass before rabies symptoms become apparent in an infected individual.

Rabies virus proliferates in the brain, especially in the thalamus and hypothalamus. Infection leads to fever, excitation, dilation of the pupils, excessive salivation, and anxiety. In advanced rabies, swallowing triggers uncontrollable spasms of the throat muscles when victims try to drink, ultimately leading to a fear of even the sight of water, a condition called *hydrophobia* (an early name for rabies). Death of rabies victims eventually results from respiratory paralysis. In humans, an *untreated* rabies infection in which symptoms have begun is almost always fatal. Fortunately for both domestic animals and humans, an effective rabies vaccine exists, and this keeps the incidence of rabies low in domestic animals (Figure 32.1a) and a rarity in humans in developed countries.

Mastering Microbiology
Art Activity:
Figure 32.2
Rabies virus

Figure 32.1 Rabies cases in wild and domestic animals in the United States. (a) Incidence of rabies by year. Human cases are fewer than five per year. (b) Major vectors of rabies virus. In some areas, for example, southwest Texas, both skunks and foxes are the major vectors (shown by hatched lines). Over 90% of all reported rabies cases occur in wild animals. However, actual numbers are probably significantly higher than shown in part a because of undiagnosed cases and undiscovered rabid animal carcasses. Bats (not shown) are reservoirs of rabies virus throughout the continental United States and in Alaska. Data are from the Centers for Disease Control and Prevention, Atlanta, Georgia, USA.

Diagnosis, Treatment, and Prevention of Rabies

Rabies is diagnosed in the laboratory by examining tissue samples for the virus. Fluorescent antibodies that bind to rabies virus in brain tissues are used to confirm a case of rabies in a postmortem examination. Infected nerve cells stained for light microscopy also show viral inclusions called *Negri bodies* in their cytoplasm, and these characteristic structures confirm rabies virus infection as well (Figure 32.2b).

Figure 32.2 Rabies virus. (a) The bullet-shaped rabies virions (arrows) shown in this transmission electron micrograph of a tissue section from a rabid animal are about 75×180 nm. (b) Pathology of rabies in humans. In brain tissue, rabies virus causes characteristic cytoplasmic inclusions called Negri bodies (arrows in photomicrograph), which contain rabies virus antigens. Negri bodies are about 2–10 μ m in diameter.

Because rabies is such a serious disease, firm guidelines for treating possible human exposure to rabies have been established, and the details can be found in the rabies section of the World Health Organization website (<http://www.WHO.int>). In summary, the guidelines state that if a wild or stray animal is suspected of being rabid, it should be immediately examined for evidence of the rabies virus. If a domestic animal, generally a dog, cat, or ferret, bites a human, especially if the bite is unprovoked, the animal should be held in quarantine for 10 days to check for signs of rabies. If the animal exhibits rabies symptoms, or if a definitive diagnosis of its illness cannot be made after 10 days (or if the animal could not be retained for examination), the human should be passively immunized with rabies immune globulin (purified human antibodies to rabies virus) injected at both the site of the bite and intramuscularly. The patient should also be actively immunized with a rabies virus vaccine. Because of the very slow progression of rabies in humans, this combination of passive and active immune therapy (◀ Section 27.2) is nearly 100% effective, stopping the onset of the disease.

Rabies is prevented largely through immunization. An inactivated rabies vaccine is used in the United States for both humans and domestic animals. Prophylactic rabies immunization is practiced for individuals at high risk, such as veterinarians, animal control personnel, animal researchers, and individuals who work in rabies research or rabies vaccine production laboratories. The rabies problem is primarily with wild animals (Figure 32.1), where traditional means of vaccination are impossible. However, experimental trials with an oral rabies vaccine administered in food “baits” have reduced the incidence and spread of rabies in limited geographic areas. If herd immunity (◀ Section 30.2) could be established in some of the key carriers of rabies (Figure 32.1b), it might be possible

to reduce incidence of the disease dramatically. Some regions, such as Hawaii and Great Britain, are rabies-free, and any animal imported into these areas is subject to temporary quarantine to ensure the animal is healthy.

Although rabies is vaccine-preventable, nearly 60,000 people per year die from rabies worldwide, primarily in developing countries in Africa and Asia where rabies is enzootic in domestic animals because of inadequate vaccination practices. Worldwide, nearly 14 million people receive prophylactic treatment for rabies after exposure annually, and in the United States, over 20,000 individuals receive such treatment. Fewer than five cases of human rabies are reported in the United States each year, nearly always the result of bites from wild animals, most frequently from bats. Because domestic animals often have exposure to wild animals, dogs and cats are routinely vaccinated against rabies beginning at 3 months of age. Large farm animals, especially horses, are often immunized against rabies as well. One other rare but possible mode of rabies transmission is from organ and tissue transplants. In 2013, a rabies death in the U.S. was linked to a transplanted kidney received from a donor who died from rabies that was misdiagnosed as severe gastroenteritis. Past cases of rabies transmission in a cornea and other transplants have also been documented where the donor had yet to show signs of clinical rabies.

- What is the procedure for treating a human bitten by an animal if the animal cannot be found?
- What major advantage does an oral vaccine have over a parenteral (injected) vaccine for rabies control in wild animals?

32.2 Hantavirus and Hantavirus Syndromes

Hantaviruses cause two severe, emerging diseases, **hantavirus pulmonary syndrome (HPS)**, an acute respiratory and cardiac disease, and **hemorrhagic fever with renal syndrome (HFRS)**, an acute disease characterized by shock and kidney failure. Both diseases are caused by hantaviruses transmitted from infected rodents. Hantavirus is named for Hantaan, Korea, the site of a hemorrhagic fever outbreak where the virus was first recognized as a human pathogen.

Symptoms and Pathology of Hantavirus Syndromes

Similar to influenza viruses, hantaviruses are enveloped viruses (**Figure 32.3a**) having single-stranded minus-sense RNA genomes arranged in segments (◀ Section 11.9). However, hantaviruses are genetically and functionally more closely related to other hemorrhagic fever viruses, such as Lassa fever virus and Oropouche fever virus (Table 32.1). Hantaviruses asymptomatically infect an estimated 10–15% of rodents, including mice, rats, lemmings, and voles. The virus is transmitted from these reservoirs to humans by inhalation of virus-contaminated rodent excreta. Humans are accidental hosts and are infected only when they come into contact with rodents, their waste, or their saliva.

HPS is characterized by a sudden onset of fever, nausea, muscle pain, a reduction in the number of blood platelets along with an increase in the number of circulating leukocytes, and hemorrhaging. Death (if it occurs) takes several days, and it is usually a result of

systemic shock and cardiac complications precipitated by leakage of fluid into the lungs, causing suffocation and heart failure. These symptoms are typical of hantaviruses, but other symptoms such as kidney failure are common, depending on the strain of virus causing the disease. HFRS is characterized by intense headache, back and abdominal pain, renal dysfunction, and various hemorrhagic complications. HFRS strains are most prevalent in hantavirus outbreaks in Eurasia, whereas HPS strains are more prevalent in the Americas. At nearly 40%, the mortality rate for HPS strains is significantly higher than for HFRS strains (1–15%).

Hantaviruses can be cultured in the laboratory, but because of the danger involved, they must be handled with precautions for bio-safety level 4 (BSL-4; ◀ Section 29.1). In the world of infectious diseases, hantavirus, Ebola, and other BSL-4 viral pathogens are considered “the worst of the worst” and are thus handled in the United States by the Viral Special Pathogens Branch of the Centers for Disease Control and Prevention in Atlanta (Georgia, USA).

Epidemiology, Diagnosis, and Prevention of Hantavirus Syndromes

A significant HPS outbreak in the United States occurred near the Four Corners region of Arizona, Colorado, New Mexico, and Utah in 1993. The outbreak resulted from an enlarged population of deer mice in the spring of 1993. The previous winter was mild and was followed by abundant spring rains, triggering unusually high food levels for the mice. The HPS outbreak caused 27 deaths among 48 infected people (56% mortality), illustrating the potential danger of outbreaks due to pathogens that can be directly transmitted from animal reservoirs. In total from 1993 to January 2017, there were 728 cases of HPS in the United States, with 262 deaths (36% mortality), mostly in western states. On a global basis, it is estimated that 200,000 infections occur annually, chiefly in China, Korea, and Russia, but mortality rates are typically low.

Hantavirus syndromes can be diagnosed using immunological techniques that identify anti-hantavirus antibodies in a blood

Figure 32.3 Hantavirus. (a) A transmission electron micrograph of the Sin Nombre hantavirus. The arrow indicates one of several virions that are about 100 nm in diameter. (b) Immunofluorescent staining of Andes hantavirus antigens in alveolar macrophages. Each granular dark blue-stained area indicates cellular infection of an individual macrophage that contains many hantavirus virions (each cell is about 15 μ m in diameter).

sample. These include immunoassays (Figure 32.3*b* and ◀ Section 29.5) that detect both exposure to the virus and the strength of the immune response. The presence of the viral RNA genome from circulating virions can also be detected using RT-PCR (◀ Sections 12.1 and 29.8) on patient tissue or blood samples.

There is no virus-specific treatment or vaccine for hantavirus diseases. Treatment amounts to isolation, rest, rehydration, and alleviation of other symptoms. Hantavirus infection can be prevented by avoiding rodent contact and rodent habitat. Destruction of mouse habitat, restricting food supplies (for example, keeping human food in sealed containers), and aggressive rodent extermination measures are the only effective controls; animal surveys have shown that areas that have experienced a hantavirus outbreak have a high proportion of mice that carry the virus.

Check Your Understanding

- Why might hantaviruses be considered a serious public health threat in the United States?
- Describe the spread of hantaviruses to humans. What are some effective measures for preventing infection by hantaviruses?

II • Arthropod-Transmitted Bacterial and Viral Diseases

Athropods such as mosquitoes and ticks are reservoirs for a diversity of pathogenic bacteria and viruses that infect humans, and these microbes are responsible for considerable human morbidity and mortality anywhere these animal vectors exist.

Pathogens can be spread to new hosts from the bite of an infected arthropod. In the bacterial and viral diseases we consider here—the rickettsial illnesses; yellow and dengue fevers; Lyme, Chikungunya, and Zika virus diseases; and plague—humans are only *accidental hosts* for the pathogen. The *reservoir* of the pathogen is the arthropod vector (Table 32.1). Nevertheless, the diseases can be devastating and often fatal.

32.3 Rickettsial Diseases

The **rickettsias** are small *Bacteria* that live an obligate intracellular existence and are associated with bloodsucking arthropods such as fleas, lice, or ticks. We discussed the biology of rickettsias in Section 16.1. Of the diseases that rickettsias can cause in humans and other vertebrates, the most important are *typhus fever*, *spotted fever rickettsiosis* (*Rocky Mountain spotted fever*), and *ehrlichiosis*. Rickettsias have not been cultured in artificial culture media but can be grown in laboratory animals, ticks and lice, mammalian tissue culture cells, and the yolk sac of chick embryos (see Figure 32.6*b*). In animals, growth takes place primarily in phagocytes, such as macrophages.

Rickettsias are divided into three groups based on the clinical diseases they cause: (1) the *typhus group*, such as *Rickettsia prowazekii*; (2) the *spotted fever group*, such as *Rickettsia rickettsii*; and (3) the *ehrlichiosis group*, characterized by *Ehrlichia chaffeensis*, and we examine the pathobiological features of each of these now.

The Typhus Group: *Rickettsia prowazekii*

Typhus is transmitted from person to person by the common body or head louse (Figure 32.4*a*), and humans are the only known mammalian host. During World War I, a typhus epidemic spread throughout Eastern Europe and caused almost 3 million deaths. Typhus has historically been a problem among troops in wartime. Because of the unsanitary, cramped conditions characteristic of wartime military operations, infected lice can spread easily among soldiers with devastating results. Up until World War II, typhus caused more military deaths than did combat.

Cells of *R. prowazekii* are introduced through the skin when a puncture caused by a louse bite becomes contaminated with louse feces that contain the rickettsial cells. During an incubation period of 1–3 weeks, the organism multiplies inside cells lining the small blood vessels. Symptoms of typhus, such as fever, headache, and general body weakness, then begin to appear. Several days later, a characteristic rash is observed in the armpits and generally spreads over the body, except for the face, palms of the hands, and soles of the feet. Complications from untreated typhus include damage to the central nervous system, lungs, kidneys, and heart. Epidemic typhus has a mortality rate of as much as 30%. Tetracycline and chloramphenicol are most commonly used to control infections caused by *R. prowazekii*. *Rickettsia typhi*, the organism that causes murine (mouse) typhus, is another important pathogen in the typhus group and can also infect humans. A typhus vaccine is available but is typically only administered to those traveling to typhus endemic areas, such as certain parts of Africa and South America.

Mastering
Microbiology

Art Activity:
Figure 32.5
Spotted fever
rickettsiosis
(Rocky
Mountain
spotted fever)
in the United
States, 2010

The Spotted Fever Group: *Rickettsia rickettsii*

Spotted fever rickettsiosis (SFR), also called *Rocky Mountain spotted fever*, was first recognized in the western United States about 1900, but it is more prevalent today in the eastern and mid-South region (Figure 32.5). SFR is caused by *R. rickettsii* and is transmitted to humans by various ticks, most commonly the dog tick (Figure 32.4*b*) and wood ticks. The incidence of SFR has been increasing steadily for two decades, with reported cases in the United States increasing from just 500 in the year 2000 to over 6000 in 2017. The emergence of SFR is attributed to increased outdoor recreational activities, such as hiking and camping, in tick-infested areas. Fatalities in treated

Figure 32.4 Arthropod vectors of rickettsial diseases. (a) The female body louse, about 3 mm long, can carry *Rickettsia prowazekii*, the agent that causes typhus. In addition, the body louse can carry *Borrelia recurrentis*, the agent of relapsing fever, and *Bartonella quintana*, the agent of trench fever. (b) The American dog tick that carries *Rickettsia rickettsii*, the causative agent of spotted fever rickettsiosis, is about 5 mm long, but can expand to three times this size when engorged with blood.

Figure 32.5 Spotted fever rickettsiosis (Rocky Mountain spotted fever) in the United States, 2017. Despite the name, cases of Rocky Mountain spotted fever are currently concentrated in the eastern and mid-South states from Oklahoma to North Carolina.

patients occur in less than 1% of those infected. Humans acquire the pathogen from the bite of an infected tick; rickettsial cells are present in the salivary glands of the tick and in the ovaries of female ticks.

Cells of *R. rickettsii*, unlike other rickettsias, grow within the nucleus of the host cell as well as in host cell cytoplasm (Figure 32.6a, c). Following an incubation period of 3–12 days, characteristic symptoms, including fever and a severe headache, occur. A few days later, a systemic rash breaks out (Figure 32.6d) that is distinguished from typhus and viral rashes because it extends over the whole body, even the palms of the hands and soles of the feet. The rash is often accompanied by gastrointestinal complications, such as diarrhea and vomiting. The clinical symptoms of SFR persist for over 2 weeks if the disease is untreated. Tetracycline or chloramphenicol generally promotes a prompt recovery from SFR if administered early in the course of the infection. Mortality in untreated cases of SFR resembles that of typhus, up to 30%. No effective vaccine against SFR is currently available.

Ehrlichiosis and Tickborne Anaplasmosis

Ehrlichia and related genera (Section 16.1) are responsible for two emerging tickborne diseases in the United States, *human monocytic ehrlichiosis* (HME) and *human granulocytic anaplasmosis* (HGA). The pathogens that cause HME are *Ehrlichia chaffeensis* and *Rickettsia sennetsu*, and those that cause HGA are *Ehrlichia ewingii* and *Anaplasma phagocytophilum*.

The onset of these clinically indistinguishable rickettsial diseases is characterized by flulike symptoms that can include fever, headache, malaise, changes in liver function, and a reduction in white blood cell numbers. Peripheral blood leukocytes such as monocytes have visible inclusions of rickettsial cells, a diagnostic indicator for the diseases (Figure 32.7a). The symptoms, except for the inclusions, are similar to other rickettsial infections and can range from subclinical to fatal. Long-term complications for progressive untreated cases may include respiratory and renal insufficiency and serious neurological involvement.

HGA and HME are spread by ticks of various species, and mammalian reservoirs of the pathogens include deer, some rodents, and humans. In the United States, HGA occurs primarily in the upper Midwest and coastal New England, while HME is concentrated in the lower Midwest and the East Coast. Similar to SFR, the incidence of HME and HGA have steadily risen over the past 20 years, and together, about 6000 cases are reported each year, with cases of HGA predominating. Diagnosis of rickettsial syndromes is not straightforward because the rash observed can be mistaken for other diseases, such as scarlet fever, or even measles or syphilis. Confirmation of a rickettsial disease requires immunological tests, including fluorescent antibodies or immunoassays, or PCR-based analyses that detect pathogen DNA.

Prevention of HGA and HME is best achieved either by avoiding tick habitat or by wearing tick-proof clothing and applying insect repellents containing diethyl-*m*-toluamide (DEET). It is also good practice to examine yourself carefully for ticks after hiking in tick habitat and to remove any ticks immediately, taking care to remove all tick mouthparts if the tick has already attached. Doxycycline, a tetracycline antibiotic, is the drug of choice for the treatment of HGA and HME. Vaccines are currently unavailable for the prevention of HGA and HME.

Figure 32.6 *Rickettsia rickettsii* and spotted fever rickettsiosis. (a) Cells of *R. rickettsii*, growing in the cytoplasm and nucleus of tick hemocytes and (b) in chicken egg yolk sacs; cells are about 0.4 μm in diameter. (c) Transmission electron micrograph of *R. rickettsii* (arrows) in a granular hemocyte of an infected wood tick. (d) Rash of spotted fever rickettsiosis on the feet. The whole-body rash is indicative of spotted fever rickettsiosis and helps distinguish it from typhus, in which the rash does not cover the whole body.

(a)

(b)

Figure 32.7 Ehrlichia and Coxiella. (a) *Ehrlichia chaffeensis*, the causative agent of human monocytic ehrlichiosis (HME). The electron micrograph shows inclusions in a human monocyte that contains large numbers of *E. chaffeensis* cells. The blue arrows indicate bacteria in each inclusion. The *E. chaffeensis* cells are about 0.3–0.9 μm in diameter. Mitochondria are indicated by red arrows. (b) Colorized scanning electron micrograph of cells of *Coxiella burnetii*, the causative agent of Q fever. The *Coxiella* cells were grown in animal cell culture and are shown inside a lysed host cell. A single *C. burnetii* cell is about 0.4 μm in diameter.

Q Fever

Q fever (the Q stands for “query”) is a pneumonia-like infection caused by the intracellular parasite *Coxiella burnetii* (Figure 32.7b), a bacterium related to the rickettsias (◀ Section 16.1). Although not transmitted to humans by an insect bite, *C. burnetii* cells are transmitted to animals such as sheep, cattle, and goats by insect bites, and from these reservoirs are transmitted to humans. Domestic animals generally have asymptomatic infections but may shed large quantities of *C. burnetii* cells in their urine, feces, milk, and other body fluids. Infected animals or contaminated animal products such as wool, meat, and milk are potential sources for human infection. The resulting influenza-like illness can progress to include prolonged fever, headache, chills, chest pains, pneumonia, and endocarditis (inflammation of the inner lining of the heart). In the United States, Q fever is most prevalent in rural states with large farm or ranch animal populations, and about 150 cases have been reported annually in recent years.

As for rickettsial infections, laboratory diagnosis of *C. burnetii* infection is typically made by immunological tests designed to measure host antibodies to the pathogen. Q fever responds well to tetracycline, and therapy should be started quickly in any suspected case to prevent endocarditis and heart valve damage. *C. burnetii* is also a potential biological warfare agent (◀ Section 30.9).

Unlike its relatives in the *Rickettsia* group, the Q fever pathogen *C. burnetii* can now be grown in pure culture outside a host. This was accomplished by considering both the resources and conditions likely to exist in the intracellular host environment along with a careful analysis of the *C. burnetii* genome sequence to reveal the metabolic capacities and limitations of this pathogen. One major discovery gleaned from genomic analysis of the *C. burnetii* complement of cytochromes was the fact that the organism was likely to be microaerophilic (◀ Section 4.16). Indeed, one of the keys to its axenic (pure) culture was to incubate cultures under low oxygen

tensions, which is somewhat surprising considering that host cells should be fully oxic.

Check Your Understanding

- What are the arthropod vectors and animal hosts for typhus, spotted fever rickettsiosis, ehrlichiosis, and anaplasmosis?
- What precautions can be taken to prevent rickettsial infections?

32.4 Lyme Disease and *Borrelia*

Lyme disease is a tickborne disease that affects humans and other animals. Lyme disease was named for Old Lyme, Connecticut, where cases were first recognized, and is currently the most prevalent arthropod-borne disease in the United States. Lyme disease is caused by infection with a spirochete, *Borrelia burgdorferi* (Figure 32.8; ▶ Section 15.17), transmitted by a tick bite. The ticks that carry *B. burgdorferi* feed on the blood of birds, domesticated animals, various wild animals, and humans. *B. burgdorferi* is of interest in a nonmedical way, as well, because it is one of only a handful of *Bacteria* that contain a linear (as opposed to a circular) chromosome (◀ Section 6.2).

Pathology, Diagnosis, and Treatment of Lyme Disease

Cells of *B. burgdorferi* are transmitted to humans while the tick is obtaining a blood meal (Figure 32.9a). A systemic infection develops, leading to the acute symptoms of Lyme disease: headache, backache, chills, and fatigue. In about 75% of Lyme cases, a concentric circular or “bull’s-eye” rash forms within a week at the site of the tick bite (Figure 32.9b). During this acute stage, Lyme disease is readily treatable with tetracycline or penicillin.

Untreated cases of Lyme disease may progress to a chronic stage weeks to months after the initial tick bite, causing arthritis in about half of those infected. Neurological problems such as palsy,

Figure 32.8 The Lyme disease spirochete, *Borrelia burgdorferi*. (a) Fluorescent antibody staining (◀ Section 29.6) of cells of *B. burgdorferi* from a Lyme disease rash. Two different fluorescent antibodies were used, each specific for a different *B. burgdorferi* antigen and linked to either an orange or a green fluorescent tag. If both antibodies bind, cells appear yellow. (b) Colorized scanning electron micrograph of cells of *B. burgdorferi*. A single cell is approximately 0.4 μm in diameter and 5–20 μm long.

weakness in the limbs, and heart damage can also occur. In untreated cases, cells of *B. burgdorferi* infecting the central nervous system may lie dormant for long periods before causing additional chronic symptoms, including problems with vision and facial muscle movements, or seizures. Interestingly, the neurological symptoms of chronic Lyme disease mimic those of chronic syphilis, which is caused by a different spirochete, *Treponema pallidum* (◀ Sections 15.17 and 31.13). Unlike syphilis, however, Lyme disease is not spread person to person.

No toxins or other major virulence factors have been identified in Lyme disease pathogenesis, but the pathogen triggers a strong

immune response. Antibodies to *B. burgdorferi* appear 4–6 weeks after infection and can be detected by various immunological assays. However, because antibodies to *B. burgdorferi* antigens persist for years after infection, the presence of these antibodies does not necessarily indicate a recent infection. A PCR assay (◀ Sections 12.1 and 29.8) is also in use to detect *B. burgdorferi* DNA in body fluids and tissues. In practice, however, Lyme disease is typically diagnosed from clinical symptoms and only confirmed later by laboratory assays. If a patient has had recent tick exposure and presents Lyme disease signs and symptoms, such as facial tics, arthritis, or the characteristic Lyme rash (Figure 32.9b), a presumptive diagnosis of Lyme disease is made and antibiotic treatment is initiated.

Treatment of early-stage Lyme disease is usually with doxycycline or amoxicillin for 20 to 30 days. For patients having neurological or cardiac symptoms, the antibiotic ceftriaxone is administered intravenously because this drug crosses the blood–brain barrier and thus can kill spirochetes in the central nervous system.

Epidemiology and Prevention of Lyme Disease

White-footed field mice and other small rodents are the major mammalian reservoir of *B. burgdorferi* in the northeastern United States, a hotbed of Lyme infection (see Figure 32.11). These animals become infected from bites by the deer tick, *Ixodes scapularis* (Figure 32.10), although some other ticks can transmit the Lyme spirochete as well. Deer themselves are not *B. burgdorferi* reservoirs but are major reproductive hosts for the tick. Lyme disease has also been identified in Europe and Asia. In these countries, both the tick vector and the species of *Borrelia* differ from those in the United States, which shows that Lyme disease has a broad geographic distribution. In all cases, however, Lyme disease is caused by related species of pathogenic *Borrelia* transmitted to humans by tick vectors.

Deer ticks are typically smaller than many other ticks (Figure 32.9a), making them easy to overlook. Moreover, unlike the case with ticks that carry other tickborne diseases (Figure 32.4b), a high percentage of deer ticks carry *B. burgdorferi*. Both of these factors—small vector size and high occurrence of the pathogen—undoubtedly contribute to the fact that Lyme is the most commonly reported vectorborne disease in the United States (Figure 32.11). Most cases of Lyme disease in the United States have been reported from the Northeast and upper Midwest—areas of the country where deer

Figure 32.9 Lyme disease infection. (a) A deer tick (here, blood-engorged) obtaining a blood meal from a human is the route of disease transmission (see Figure 32.10 for photos of deer ticks). The tick is about the size of the head of a pin (about 1 mm in diameter). (b) Characteristic “bull’s-eye” rash of Lyme disease. The rash starts at the site of a tick bite and grows in a concentric circular fashion over a period of several days. A typical rash is 5–8 cm in diameter.

Figure 32.10 Deer ticks, the major vector of Lyme disease. Left to right, male and female adult ticks, nymph, and larva forms. The length of an adult female is about 3 mm. Although all forms feed on humans, the female nymphal and adult ticks are principally responsible for transmitting *Borrelia burgdorferi*.

Figure 32.11 Lyme disease in the United States, 2017. Each dot represents a confirmed case. Confirmed and probable cases in 2017 totaled nearly 43,000, with about 95% of these localized to 13 states in the upper regions of the Midwest and East Coast. Lyme disease is reported through the National Notifiable Diseases Surveillance System of the Centers for Disease Control and Prevention, Atlanta, Georgia, USA.

and wooded areas are abundant—but cases have been observed throughout North America (Figure 32.11). The incidence of Lyme disease in the United States is significant, with 42,743 confirmed and probable cases reported in 2017.

As for any tickborne infection, prevention of Lyme disease begins by avoiding contact with the vector. Insect repellents containing DEET or the wearing of snug-fitting clothing is helpful, as is a thorough body exam following walks in tick-infested environments. Lyme disease vaccines are available for domestic animals, but no human Lyme disease vaccine is currently in use.

32.5 Yellow Fever, Dengue Fever, Chikungunya, and Zika

Several arthropod-transmitted diseases are caused by flaviviruses. These are single-stranded plus-sense RNA viruses (◀ Section 11.8) transmitted by the bite of an infected arthropod. Because of this characteristic mode of transmission, these viruses are also called *arboviruses* (arthropod-borne viruses).

Many serious human diseases are caused by arboviruses including various types of encephalitis and hemorrhagic fevers. Here we consider two potentially fatal flavivirus diseases common in some tropical and subtropical regions: yellow fever and dengue fever. Some of the symptoms of these diseases are similar, and both viruses are transmitted by the same vector, female mosquitoes of the genus *Aedes* (Figure 32.12). This insect vector infects nearly half a billion people each year with dangerous viral pathogens, which, in addition to yellow fever and dengue viruses, include Zika and Chikungunya viruses.

Yellow Fever

Yellow fever is an endemic disease of tropical and subtropical climates, especially in Latin America and Africa. Brazil, Colombia, Venezuela, and parts of Bolivia and Peru, along with most countries in sub-Saharan central Africa, experience the greatest incidence. Yellow fever is absent from the United States except in unvaccinated individuals who contract the disease through travel to an endemic area. Yellow fever virus is related to dengue virus (see later), West Nile virus (Section 32.6), and certain encephalitis viruses. Yellow fever is one of only a handful of infectious diseases for which isolation and quarantine are practiced (◀ Section 30.5). In the case of yellow fever, although the disease is not transmitted person to person, isolation of active cases prevents local mosquitoes from taking a blood meal from the infected individual and transmitting the disease to others.

Following a bite from an infected mosquito, the yellow fever virus replicates in lymph nodes and certain immune system cells and eventually travels to the liver. Once a person is infected, symptoms range anywhere from none to major organ failure and death. Most infected individuals display a mild fever with accompanying chills, a headache and back pains, nausea, and other symptoms that are not diagnostically useful. Presumably these are cases in which the immune system has the infection under control. However, in about one in five yellow fever cases, the disease enters its toxic phase, characterized by jaundice (thus the name *yellow fever*) and by hemorrhaging from the mouth, eyes, and gastrointestinal tract. This triggers the onset of bouts of bloody vomit, and if bleeding continues, it leads to toxic shock and multiple organ failure. About 20% of cases that reach this stage are fatal. Humans and nonhuman primates are the main reservoirs for the yellow fever virus.

Yellow fever is fully preventable by an effective vaccine. An attenuated yellow fever vaccine was developed in the 1930s (◀ Figure 25.10) and widely used by military and support personnel in tropical battlefields. Historically, the disease has been controlled by a combination of vaccination and elimination of both the vector (mosquito) population by chemical agents and vector breeding grounds by draining swamps and low-lying wetlands in endemic areas.

The yellow fever vaccine is highly recommended for those traveling to endemic areas, and many countries require proof of vaccination for anyone entering their country from a foreign country where yellow fever is endemic. In addition, the World Health Organization (WHO) has initiated a mass vaccination program in Africa. Despite the availability of a vaccine, the WHO estimates that each year nearly 200,000 cases of yellow fever occur, mostly unreported, and that about 30% of all cases are fatal. Other than palliative care, no treatment for yellow fever is available. Once the disease is diagnosed, typically by detecting anti-yellow fever virus antibodies in a blood sample, the patient is isolated and prescribed rest and drugs to control symptoms. Recovery without entering the toxemia stage is due to the immune response.

Dengue Fever

Like yellow fever, dengue (pronounced deng-gay) fever is transmitted by mosquitoes of the genus *Aedes* (Figure 32.12) and is a disease of tropical and subtropical regions. It is estimated that as much as *one-half* of the world's population lives in areas where dengue is endemic, and therefore it is no surprise that it is the most common vectorborne

Figure 32.12 Yellow fever and dengue fever. (a) Yellow and dengue fever viruses are both transmitted by the bite of an infected *Aedes aegypti* mosquito. Transmission electron micrographs of (b) yellow fever virus and (c) dengue fever virus (arrows, in a tissue specimen). Both yellow and dengue fever viruses are about 50 nm in diameter and are plus-sense RNA viruses that replicate by way of polyprotein formation, as in poliovirus (◀ Figure 11.21).

disease in humans. About 100 million cases of dengue fever occur worldwide per year, with concentrations in Mexico, Central and South America, India, Indonesia, and Africa (◀ Figure 30.11).

Dengue begins with a high fever and headache or joint pains and in some patients, severe eye pain and a systemic rash. Most infected individuals show self-improvement within a week and no further symptoms, presumably because of an immune response to the dengue virus. But, as for yellow fever, a dengue infection can take a more severe course of events and proceed to *dengue hemorrhagic fever*. This condition is characterized by severe symptoms that can include bleeding from the nose and gums, bloody vomit and/or feces, intense abdominal pain, respiratory distress, and a general feeling of malaise. The blood pressure of a dengue patient can drop dramatically during the hemorrhagic fever stage, and a small percentage of these cases are fatal. Treatment for dengue is primarily to relieve symptoms, particularly dehydration from fever and loss of blood and other fluids.

A live recombinant vaccine (◀ Sections 12.8 and 28.3) marketed as Dengvaxia® is available for dengue in high-risk regions. However, because the vaccine has been shown to increase the risk of severe infection in those never before exposed to the virus, its use is restricted only to those that have already had a confirmed case of dengue fever (the same individual can be infected more than once with dengue virus). Because there is currently no point-of-care rapid diagnostic test to confirm prior exposure, use of the vaccine is significantly limited.

Dengue can be controlled by eliminating either the vector or contact with the vector. Extensive chemical spraying for mosquito eradication was widely practiced in urban centers of the southern United States and kept dengue in check in the twentieth century. Now, however, spraying programs are less common and global climate change is moving tropical temperature patterns northward. In response, the *Aedes* mosquito has become entrenched in southern and central regions of the United States. Besides *Aedes aegypti* (Figure 32.12a), the Asian tiger mosquito (*Aedes albopictus*), which is spreading quickly in the United States, also carries the dengue virus. Drainage of small sources of stagnant water, such as those in discarded tires or clogged gutters, removes mosquito breeding grounds and greatly reduces the opportunities for a dengue outbreak. Personal protection from mosquito bites by using effective insect repellents and clothing is also a proven means of preventing infection.

A recent strategy to control mosquito populations (and thus mosquito-borne disease transmission) is to employ the endosymbiotic bacterium *Wolbachia* (a close relative of *Rickettsia* and *Ehrlichia*) to control the reproductive success of the mosquito vector (◀ Section 23.7). Male mosquitoes infected with *Wolbachia* bacteria produce sperm that express proteins that render uninfected females infertile upon mating. Although not fully understood, the *Wolbachia*-derived proteins in the sperm activate a molecular switch that prevents mosquito reproduction by inhibiting embryo development. When *Wolbachia*-infected male mosquitoes are purposely released in areas where dengue is endemic, the incidence of dengue has decreased significantly, presumably because of reductions in the size of the local mosquito population.

The WHO estimates that nearly a half million cases of dengue hemorrhagic fever occur yearly with over 20,000 being fatal. Cases of dengue in the United States are rare, and many of them are imported from endemic areas. Dengue is a prime example of an emerging disease (◀ Section 30.7), as cases were geographically restricted until the mid-twentieth century when global commerce is thought to have transmitted species of the *Aedes* mosquito beyond their original range.

Zika and Chikungunya Disease

Zika and Chikungunya are both typically mild viral diseases transmitted by the same mosquito vector (Table 32.1). Zika virus disease is characterized by headache, fever, joint pain, and general malaise, and a rash is occasionally seen. The disease is caused by the Zika virus (Figure 32.13a), a relative of the dengue virus. Zika first emerged over 65 years ago in the Zika forest (Uganda), and occasional small outbreaks occurred periodically in west central Africa and Indonesia. Zika appeared in Brazil in 2015, and by 2016, outbreaks of Zika virus disease were reported in the United States, primarily in individuals who had traveled to areas with endemic disease. However, a major outbreak in the U.S. territory of Puerto Rico has been linked to local mosquito-borne transmission, and the disease may spread northward within the range of the *Aedes* mosquito. Zika infections have been reported in Florida in recent years and may eventually spread to other regions of the southern United States.

Besides vectorborne transmission, Zika can be transmitted through sexual contact and by contaminated blood and, of most concern, from mother to fetus. The incidence of brain abnormalities, especially microcephaly, and other birth defects have been linked to

Figure 32.13 Zika and Chikungunya viruses. Both viruses contain single-stranded plus-sense RNA genomes and are surrounded by an envelope (◀ Sections 5.1, 5.2, and 11.8). (a) Colorized transmission electron micrograph of virions of the Zika virus embedded in a tissue sample. A single virion (shown in blue, arrow) is about 40 nm in diameter. (b) Colorized transmission electron micrograph of virions of Chikungunya virus (arrow). A virion is about 50 nm in diameter.

infants born to Zika-infected mothers, and so Zika in some way affects development of the fetus. It is known that the Zika virus readily infects a type of neural cell that eventually forms the cerebral cortex, a major part of the brain that governs intellectual capacity, and this likely leads to the brain defects observed in Zika-infected newborns. This danger has led to advisories for pregnant women to take great precautions to avoid contact with mosquitoes during the entire pregnancy period. Other than in pregnant women, Zika virus disease seems to be a rather mild, self-limiting infection. However, in rare instances, Zika infection may trigger Guillain-Barré syndrome, an autoimmune disease (◀ Section 28.1) caused by an infection with any of several different viruses and bacteria that results in the immune system attacking the peripheral nervous system.

Too little is known about the Zika virus and the various conditions it can or might cause to draw firm conclusions about the seriousness of this threat to public health, but it is clear that the virus is capable of causing explosive epidemics under certain conditions. Deaths directly attributable to a Zika infection have been rare, and thus the pathogen seems to be of only passing concern to the general public, even in the typical high-risk groups for infectious diseases, such as the very young or very old. However, the birth defect

connection is extremely serious. Currently, it seems that pregnant women (or those trying to get pregnant, as Zika can also be transmitted by sexual intercourse) are the only group known to be at serious risk from Zika infection. No Zika vaccine is currently available, but several candidate vaccines are in development.

Like Zika, Chikungunya disease is caused by a single-stranded plus-sense RNA virus (Figure 32.13b), but the virus, of the family *Togaviridae*, is not closely related to the Zika, dengue, and yellow fever viruses (Table 32.1). Chikungunya virus is transmitted by species of *Aedes* mosquitoes and is currently endemic in South and Central America, Southeast Asia, central Africa, and Indonesia. Thus far, cases of Chikungunya in the United States have been limited to travelers returning from endemic areas, and in 2017, a total of 156 confirmed cases were reported. As for Zika, mortality in Chikungunya disease is rare, about 0.1% of all cases. The symptoms of Chikungunya are mild and self-limiting and the immune response to the virus is strong, conferring active immunity against reinfection. Unlike with Zika, no direct connection between Chikungunya viral infection and birth defects has been observed because Chikungunya virus is not transmitted from mother to fetus.

- Why is Zika virus disease considered dangerous even though it rarely kills?

32.6 West Nile Fever

West Nile virus (WNV) causes **West Nile fever**, a seasonal, human viral disease that is transmitted through a variety of mosquito vectors (Figure 32.14a). Like the yellow fever, dengue, and Zika viruses, WNV is a flavivirus (Table 32.1) having an enveloped capsid (Figure 32.14b) and containing a plus-sense single-stranded RNA genome (◀ Section 11.8). The virus can invade the nervous system of its endothermic (warm-blooded) hosts, which include certain species of birds and mammals.

Figure 32.14 West Nile virus. (a) The mosquito *Culex quinquefasciatus*, shown here engorged with human blood, is a West Nile virus vector. (b) An electron micrograph of the West Nile virus. The icosahedral virion is about 40–60 nm in diameter.

WNV Transmission and Pathology

WNV causes active disease in over 100 species of birds and is transmitted to different hosts by over 40 species of mosquito, including *Culex quinquefasciatus* (Figure 32.14a), which is common in central and eastern portions of the United States and in urban centers throughout the country. Infected birds develop a systemic viral infection (viremia) that is often fatal. Mosquitoes feeding on viremic birds are infected and can then infect other susceptible birds, renewing the cycle. In contrast to birds, humans and other animals are dead-end hosts for the virus because they do not develop the viremia necessary to infect mosquitoes.

Mortality rates for WNV infection are species-specific. For example, the human mortality rate from WNV is about 4%, whereas that for horses is significantly higher at nearly 40%. Most human infections are asymptomatic or mild and are not reported. After an incubation period of 3–14 days, about 20% of infected individuals develop West Nile fever, a mild illness lasting 3–6 days. The fever may be accompanied by headache, nausea, muscle pain, rash, lymphadenopathy (swelling of lymph nodes), and malaise. Less than 1% of infected individuals develop serious neurological diseases such as *West Nile encephalitis* or *West Nile meningitis* from viral replication in neural tissues (Figure 32.15). These are more common in adults over age 50, and the neural effects may be permanent. About 5% of West Nile cases that progress to these forms are fatal. Diagnosis of WNV disease includes assessment of clinical symptoms followed by confirmation by immunological tests that detect WNV antibodies in blood.

Control and Epidemiology of WNV

Human WNV disease was first identified in the West Nile region of Africa in 1937 and spread from there to Egypt and Israel. In the 1990s there were WNV outbreaks in horses, birds, and humans in African and European countries. The first North American cases of WNV were reported in the northeast United States in 1999, and in the years since, the disease has spread to every state in the continental U.S. (Figure 32.16). In the 1999–2017 period, the number of reported WNV cases per year has fluctuated wildly, from as few

Figure 32.16 Average annual incidence of West Nile disease in the United States, 1999–2017. In 2017, 2097 cases of human West Nile disease were reported, resulting in 146 deaths (7% mortality). West Nile virus is now endemic in mosquitoes and birds throughout the United States. Data are from the Centers for Disease Control and Prevention, Atlanta, Georgia, USA.

as about 20 to as many as 9800. The major U.S. foci of infection appear to be in the south-central states and the Great Plains from the Southwest to the Canadian border (Figure 32.16). West Nile disease is now enzootic in the bird population in the United States and in only low incidence in the human population, its accidental host.

Control of WNV illness is much the same as for other vectorborne diseases: Limit exposure to mosquitoes by using insect repellents or wearing tight-fitting, lighter-colored clothing. Spraying for mosquitoes has limited effectiveness, but removal of mosquito breeding grounds, particularly sources of standing water, helps control mosquito populations. A veterinary WNV vaccine is widely used in horses where the mortality risk demands it, but no human WNV vaccine is currently available.

32.7 Plague

Plague has caused more human deaths than any other bacterial disease in recorded history; only smallpox and measles have killed more among all infectious diseases. Plague is primarily a zoonosis of wild rodents, but humans can become accidental hosts when rodent populations experience a die-off and the disease vector, the rat flea, seeks alternative sources of a blood meal. Plague is caused by *Yersinia pestis*, a gram-negative, facultatively aerobic, rod-shaped, and encapsulated enteric bacterium (*Gammaproteobacteria*, ▶ Section 16.3) that is easily grown in laboratory culture (Figure 32.17).

Figure 32.17 *Yersinia pestis*. (a) Gram stain of cells of *Yersinia pestis*. The cells are about 0.8 μm in diameter. (b) Colonies of *Y. pestis* grown on blood agar.

Pathology and Treatment of Plague

The pathogenesis of plague is not clearly understood, but cells of *Y. pestis* produce several virulence factors that contribute to the disease process. The V and W antigens in *Y. pestis* cell walls are protein–lipoprotein complexes that inhibit immune cell phagocytosis. *Murine toxin*, an exotoxin (◀ Section 25.6) that is lethal for mice, is produced by virulent strains of *Y. pestis*. Murine toxin is a respiratory inhibitor that causes systemic shock, liver damage, and respiratory distress in mice. The toxin likely plays a role in human plague as well, because these symptoms are common in plague patients. *Y. pestis* also produces a highly immunogenic endotoxin (◀ Section 25.8) that may play a role in the disease process.

Plague can occur in several forms (see Figures 32.19 and 32.20). *Sylvatic plague* is enzootic among wild rodents. Plague is transmitted by several species of fleas, a main one being the rat flea *Xenopsylla cheopis* (Figure 32.18a). Fleas ingest *Y. pestis* cells in a blood meal, and the bacterium (Figure 32.18b) multiplies in the flea’s intestine. From there, the infected flea transmits the disease to rodents or humans in the next bite. The most common form of plague in humans is *bubonic plague*. In this case, cells of *Y. pestis* travel to the lymph nodes, where they replicate and cause swelling. The regional and pronounced swollen lymph nodes are called *buboes*, and the disease gets its name from these structures (Figure 32.19a). The buboes become filled with *Y. pestis* cells, and the bacterium’s capsule prevents phagocytosis and

Figure 32.18 The rat flea, a major vector of plague. (a) The rat flea *Xenopsylla cheopis* carries cells of *Yersinia pestis*. The bacterium replicates in the flea gut and (b) cells of *Y. pestis* are transmitted to a host in a flea bite. The rat flea was the major vector for the pandemics of plague that ravaged medieval Europe in the fourteenth century. Cells in part b were stained with a fluorescent antibody prepared against *Y. pestis* cell surface antigens.

Figure 32.19 Plague in humans. (a) A bubo (arrow) formed in the groin. (b) Gangrene in the hand of a plague victim.

destruction by cells of the immune system. Secondary buboes form in peripheral lymph nodes, and cells eventually enter the bloodstream, causing septicemia. Multiple local hemorrhages produce dark splotches on the skin and eventual tissue necrosis, giving plague its historical name, the “Black Death” (Figure 32.19b). If the infection is not treated quickly, the symptoms of plague (lymph node swelling and pain, prostration, shock, gangrene, and delirium) usually progress quickly, causing death within 3–5 days.

Pneumonic plague occurs when cells of *Y. pestis* are either inhaled directly or reach the lungs via the blood or lymphatic circulation. Significant symptoms are usually absent until the last day or two of the disease when large amounts of bloody sputum are produced. Greater than 90% of untreated cases of pneumonic plague result in death within 48 h. Moreover, pneumonic plague is highly contagious and can spread rapidly from person to person if those infected are not immediately isolated. *Septicemic plague* is the rapid spread of *Y. pestis* throughout the body via the bloodstream without the formation of buboes and is so severe that it usually causes death before a diagnosis can be made.

Bubonic plague can be successfully treated with streptomycin or gentamicin, administered by injection. Alternatively, doxycycline, ciprofloxacin, or chloramphenicol may be given intravenously. If treatment is started promptly, mortality from bubonic plague can be reduced to less than 5%. Pneumonic and septicemic plague can also be treated, but these forms progress so rapidly that antibiotic therapy, even if begun when symptoms first appear, is usually too late.

Plague Epidemiology and Control

Sylvatic plague is enzootic in a variety of rodents, including ground squirrels, prairie dogs, chipmunks, and mice; rats are the primary hosts in urban communities and were typically the hosts in episodes of sylvatic plague that triggered human pandemics during the Middle Ages. Fleas are intermediate hosts and vectors for plague, spreading the disease between rodent hosts and humans (Figure 32.20). Most infected rats or other rodents die soon after symptoms appear, but a small proportion of survivors develop a chronic infection, providing a persistent reservoir of *Y. pestis* cells to fuel new outbreaks.

Plague is endemic in developing countries in Africa, Asia, the Americas, and in south-central Eurasia; most cases occur in sub-Saharan

Figure 32.20 Plague epidemiology. In some wild rodents, sylvatic plague causes only a mild infection, but diseased animals remain a reservoir of *Yersinia pestis*. In rodents such as rats that act as disseminating hosts, as well as in humans, plague is often fatal. When the domestic rodent reservoir dies off in an epidemic, infected fleas seek alternate hosts in humans.

Africa. Pandemic plague was historically associated with unsanitary surroundings, a major factor supporting large rat populations. In sparsely populated rural areas, this is not so great a problem as the disease runs its course when the rodent population dies off, leaving a shortage of hosts. But in urban centers where alternative hosts (humans) are plentiful, an outbreak of sylvatic plague can set the stage for a human plague epidemic. In the United States only a handful of cases of plague are diagnosed annually, mostly in southwestern states (New Mexico, Colorado, and Arizona in particular) where sylvatic plague is enzootic among wild rodents (Figure 32.20). In 2017, only five cases of human plague were reported, with no deaths. From 2000 through 2016 exactly 100 cases were reported, including 12 fatalities.

Plague control is accomplished through good sanitation practices, surveillance and control of rodent reservoirs and vectors (fleas), isolation of active cases, and imposing quarantine on those who have had contact with diseased individuals. Improved public health practices and the control of rodent populations are the major reasons that outbreaks of plague are extremely rare in developed countries.

Check Your Understanding

- Distinguish among sylvatic, bubonic, septicemic, and pneumonic plague.
- Describe the insect vector, the natural host reservoir, and the treatment for plague.

III • Soilborne Bacterial Diseases

Soil is a reservoir for several formidable bacterial pathogens of humans, including certain species of the genera *Bacillus* and *Clostridium*. Although humans are only accidental hosts, these bacteria produce potent exotoxins that cause life-threatening illnesses.

32.8 Anthrax

Some human diseases are caused by microorganisms whose major habitat is soil (Table 32.1), and anthrax is an excellent example. We

covered some aspects of the disease anthrax in Section 30.9 in the context of its use as a potential bioterrorism or biological warfare agent. Here we focus more on the biology of the organism and the disease process.

Discovery and Properties of Anthrax

The famous pioneering medical microbiologist Robert Koch (◀ Section 1.12) first isolated the causative agent of the disease anthrax, the endospore-forming bacterium *Bacillus anthracis* (Figure 32.21). Using mice caught in the wild as experimental animals, Koch used the disease anthrax to develop his principles for linking cause and effect in infectious disease—Koch's postulates (◀ Figure 1.33). Anthrax is quickly fatal in mice, but in humans, anthrax can take on several different forms, from mild to severe skin infections to respiratory failure and death.

Anthrax is an enzootic disease (an endemic disease of animals) of worldwide occurrence. *B. anthracis* lives a saprophytic existence in soils, growing as an aerobic chemoorganotroph and forming endospores (◀ Section 2.8, Figure 32.21) when conditions warrant. From soil, cells or endospores of *B. anthracis* can become embedded in animal hair, hides, or other animal materials, or can be ingested, and from here the disease can develop, allowing *B. anthracis* to be transmitted to humans. Anthrax is primarily seen

Figure 32.21 *Bacillus anthracis*. The anthrax pathogen produces endospores. (a) Light micrograph of a malachite green-stained smear of *B. anthracis* cells showing greenish-blue endospores. (b) Colorized scanning electron micrograph of *B. anthracis* endospores. Cells of *B. anthracis* are about 1.2 μm in diameter.

in farm animals, particularly in cattle, sheep, and goats, and is transmitted from them to humans.

Forms of Human Anthrax

The disease anthrax can manifest itself in one of three forms: cutaneous (on the skin), intestinal, and respiratory (inhalation anthrax). In all forms, disease symptoms are due to two major toxins called *lethal toxin* and *edema toxin*. The different forms of anthrax show increasing severity, which is primarily a function of where in the body these toxins are excreted. Growth and toxin production by *B. anthracis* in the lymph nodes and lymphatic tissues leads to progressively worsening symptoms, beginning with a sore throat, muscle aches, and fever, and escalating to respiratory distress and systemic shock. In addition to anthrax toxins, the unusual protein capsule that surrounds cells of *B. anthracis* (Figure 32.22a) is also an important virulence factor of this pathogen, as it prevents destruction of the bacterium following phagocytosis by immune cells such as macrophages. Instead, cells of *B. anthracis* grow within the macrophage, eventually killing it and giving the bacterium access to the bloodstream.

Virtually all cases of human anthrax are *cutaneous anthrax*, where endospores of *B. anthracis* have entered through a break in the skin, germinate, and form a painless, black, and swollen pustule of necrotic tissue called an *eschar* (Figure 32.22b); the eschar is highly characteristic of the disease and allows for a firm diagnosis even though human anthrax is rarely seen in clinical medicine. In cutaneous anthrax the bacterium usually remains localized and the disease is readily treatable. Although cutaneous anthrax is fatal for about 20% of those untreated, most cases are treated because of the obvious symptoms, and thus fatalities are rare. *Intestinal anthrax* is very uncommon and is

triggered by the ingestion of endospores of *B. anthracis* (Figure 32.21b) in undercooked meat from diseased animals. Symptoms of intestinal anthrax include abdominal pain, bloody diarrhea, and ulcer-like lesions throughout the intestinal tract. The disease is still treatable at this stage, but because of its rarity, diagnoses are easily missed. As a result, about half of all cases of intestinal anthrax are fatal.

Inhalation anthrax is the most severe form of the disease and is fatal in almost every case (Figure 32.22c, d). Inhalation anthrax occurs from the inhalation of endospores of *B. anthracis* and, along with cutaneous anthrax, is an occupational hazard for farm workers that process wool and hides (inhalation anthrax is also known as “wool sorter’s disease”). In inhalation anthrax, the organism enters the bloodstream from inhaled dust or animal dander and multiplies to become systemic. The mounting toxemia from this runaway growth of *B. anthracis* triggers septic shock and fluid accumulation in the lungs (Figure 32.22c) that can kill a patient in less than a day.

Prevention and Vaccines

Complete prevention of anthrax is impossible because the reservoir of the organism is soil. However, anthrax is avoidable by limiting close exposure to farm animals and is easily treatable with antibiotics. For the cutaneous form this is a routine treatment, but antibiotic therapy is less effective in intestinal anthrax and especially in inhalation anthrax. By the time the latter is diagnosed, the disease has progressed to the point where it is usually too late to save the patient. An anthrax vaccine is available but because the disease is so rare, it is recommended only for high-risk individuals, such as scientists working with the organism, slaughterhouse or livestock workers, and military personnel (for biowarfare reasons). An effective and inexpensive anthrax vaccine is available for vaccinating livestock and is commonly used in cattle, sheep, goats, and horses.

Check Your Understanding

- What are the major virulence factors of *Bacillus anthracis*?
- What are the three forms of anthrax, and which is most dangerous?

Figure 32.22 Anthrax pathology. (a) The protein capsule of *Bacillus anthracis* cells is a major virulence factor because it prevents killing by macrophages. (b) Cutaneous anthrax, with its characteristic black scabby appearance on the neck of a patient. (c, d) Inhalation anthrax. (c) The lung fills with bacterial cells (arrows) and fluids (cleared zones). (d) From the systemic infection, *B. anthracis* cells can be found almost anywhere, including the lining of the central nervous system (arrows point to *B. anthracis* cells).

32.9 Tetanus and Gas Gangrene

Tetanus is a serious, life-threatening disease. Although tetanus is completely preventable through immunization, it still causes over 150,000 deaths per year, mostly in countries in Africa and Southeast Asia. *Gas gangrene* is caused by the growth in dead tissues of bacteria related to the tetanus pathogen, leading to a gassy putrefaction and loss of an infected limb or death from systemic shock. Both diseases are caused by clostridia.

Biology and Epidemiology of Tetanus

Tetanus is caused by an exotoxin produced by *Clostridium tetani*, an obligately anaerobic, endospore-forming rod (Figure 32.23a; ◀ Section 16.8). The natural reservoir of *C. tetani* is soil, where it is a ubiquitous resident, although it is occasionally found in the gut of healthy humans, as are other *Clostridium* species.

Cells of *C. tetani* normally gain access to the body through a soil-contaminated wound, typically a deep puncture. In the wound, anoxic conditions develop around the dead tissue and allow

Figure 32.23 Tetanus. (a) *Clostridium tetani* showing the “drumstick” appearance of sporulating cells with their terminal endospores. Cells of *C. tetani* are about 0.8 μm in diameter. (b) A tetanus patient showing the rigid paralysis characteristic of tetanus. Tetanus paralysis typically begins with the facial muscles (“lockjaw”) and descends to lower body regions.

germination of endospores, growth of the organism, and production of a potent exotoxin, the *tetanus toxin* (also called *tetanospasmin*). *C. tetani* is essentially noninvasive; its sole ability to cause disease is through toxemia, and thus tetanus is observed only as the result of untreated deep tissue injuries. The onset of tetanus symptoms may take from 4 days to several weeks, depending on the number of endospores inoculated at the time of the injury.

Pathogenesis of Tetanus

We have already examined the activity of tetanus toxin at the cellular and molecular level (◀ Section 25.6). The toxin directly affects the release of inhibitory signaling molecules in the nervous system. These inhibitory signals control the “relaxation” phase of muscle contraction. The absence of inhibitory signaling molecules results in rigid paralysis of the voluntary muscles, often called *lockjaw* because it is usually observed first in the muscles of the jaw and face. Preceding actual lockjaw, tetanus symptoms typically include mild spasms of facial muscles and muscles of the neck and upper back. Later, the paralysis extends to the torso and lower body (Figure 32.23b). When tetanus is fatal, death is usually due to respiratory failure. Mortality is relatively high, occurring in about 10% of all reported cases, and up to 50% of cases in which treatment is delayed until generalized full body tetanus has set in.

Diagnosis, Control, Prevention, and Treatment of Tetanus

Diagnosis of tetanus is based on exposure, clinical symptoms (Figure 32.23b), and, rarely, identification of the toxin in the blood or tissues of the patient. The natural reservoir of *C. tetani* is soil and thus control measures must focus on disease prevention rather than pathogen removal. The widely used tetanus toxoid vaccine is highly effective, and thus virtually all tetanus cases occur in individuals who either were never immunized or were vaccinated more than 10 years prior to exposure to the pathogen.

A second line of tetanus protection is to administer appropriate medical care to serious cuts, lacerations, and punctures. Even though vaccination against tetanus is widely practiced, any serious wound should be thoroughly cleaned and the damaged tissue removed. If the vaccination status of the individual is unclear or the last tetanus booster was more than 10 years ago, revaccination is highly recommended. If a deep wound is severe or heavily contaminated by soil,

treatment might also include administration of a tetanus antitoxin preparation, especially if the patient’s immunization status is unknown or is out of date.

Acute symptomatic tetanus (Figure 32.23b) is treated with antibiotics, usually penicillin, to stop growth and toxin production by *C. tetani*, and antitoxin is injected intramuscularly (or into the sheath surrounding the spinal cord if necessary) to prevent binding of newly released toxin to cells. Supportive therapy such as sedation, administration of muscle relaxants, and mechanical respiration may be necessary to control the effects of paralysis. Treatment cannot provide a quick reversal of symptoms because toxin that is already bound to tissues cannot be neutralized. Even with antitoxin, antibiotic administration, and supportive therapy, tetanus patients show significant morbidity and mortality. A complete recovery from tetanus often takes many months.

Gas Gangrene

Tissue destruction due to the growth of proteolytic and gas-producing clostridia is called **gas gangrene**. In this life-threatening condition, amino acids obtained from the breakdown of muscle proteins are fermented to the gases H_2 and CO_2 plus a variety of foul-smelling organic compounds, including short-chain fatty acids and other putrid molecules; ammonia released during amino acid fermentation (◀ Section 14.19) adds to the stench. In addition, a variety of bacterial toxins are produced that accelerate tissue destruction.

Although *C. tetani* is a proteolytic *Clostridium* species, it does not cause gangrene but can be associated with cases of gangrene triggered by a deep tissue wound. The most common causes of gangrene are *Clostridium perfringens* (Figure 32.24a), which is also a common cause of foodborne illness unrelated to gangrene; *C. novyi*; and *C. septicum*. These organisms reside in soil and are also part of the normal human intestinal microbiota. When these species reach deep into tissues, typically from traumatic tissue invasion such as a war wound or other puncture wound, or occasionally from gastrointestinal tract surgery, endospores and vegetative cells of proteolytic clostridia are inserted into what are now dead tissues. As the bacteria grow, they release enzymes that destroy collagen and tissue proteins

Figure 32.24 Gas gangrene. (a) Gram stain of cells of *Clostridium perfringens*, the most common cause of gangrene. (b) Flagellum stain showing a cell of *Clostridium novyi*, also an agent of gangrene. Cells of both *C. perfringens* and *C. novyi* are about 1.2 μm in diameter. (c) A case of gas gangrene on the foot.

and also excrete a series of toxins. *C. perfringens* (Figure 32.24a) α -toxin, which is distinct from the toxins the bacterium produces in perfringens food poisoning (► Section 33.9), is a major virulence factor in gangrene, as is the general ability of the pathogens to grow rapidly in the warm, moist, and protein-rich environment created by an invasive injury. *C. perfringens* α -toxin is a phospholipase that hydrolyzes the membrane phospholipids of host cells, leading to cell lysis and the typical accumulation of gas and fluids that accompanies gas gangrene (Figure 32.24c).

In severe cases of gas gangrene, the toxemia can become systemic and cause death. Antibiotic treatment is taken as a preventive measure in cases of gangrene in addition to the typical though dramatic treatment: amputation of the infected limb. Gangrenous tissues are dead and will not regenerate, and amputation prevents the infection from reaching healthy tissues.

Hyperbaric oxygen treatment of the infected limb is attempted in some cases to try to save it, with the high levels of O_2 inhibiting growth of the obligately anaerobic clostridia. In hyperbaric

treatment, the patient sits in an enclosed chamber containing 100% O_2 at about twice atmospheric pressure. This enriches the blood in O_2 and helps still-living blood vessels seed the formation of new tissue. Several hyperbaric treatments are administered and may be accompanied by surgical removal of some of the dead tissue. If an adequate blood supply can be established in damaged tissues, a skin graft may also be done to help connect regenerating tissues with damaged ones.

Check Your Understanding

- Describe infection by *Clostridium tetani* and the effects of tetanus toxin. How does the mode of action of tetanus toxin differ from that of α -toxin produced by *Clostridium perfringens*?
- Describe the steps necessary to prevent tetanus in an individual who has sustained a puncture wound.
- How does the physiology of *C. perfringens* make it suitable for growing in puncture wounds?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Animal-Transmitted Viral Diseases

- 32.1** Rabies occurs primarily in wild animals but can be transmitted to humans and domestic animals. In the United States, rabies is transmitted primarily from the wild animal reservoir to domestic animals or, very rarely, to humans. Vaccination of domestic animals is key to the control of rabies. Most human deaths from rabies occur in developing countries.

Q Which pathogen causes rabies? How does it enter the body? What are the factors that determine the incubation period before the onset of the symptoms of rabies?

- 32.2** Hantaviruses are present worldwide in rodent populations and cause zoonotic diseases such as hantavirus pulmonary syndrome and hemorrhagic fever with renal syndrome in humans. Hantavirus is a highly dangerous hemorrhagic fever virus related to Lassa fever virus. In the Americas, hantavirus infections have mortality rates of over 30%.

Q Describe the conditions that may cause emergence of hantavirus pulmonary syndrome (HPS). How can HPS be prevented?

II • Arthropod-Transmitted Bacterial and Viral Diseases

- 32.3** Rickettsias are obligate intracellular parasitic bacteria transmitted to hosts by arthropod vectors. The incidence of spotted fever rickettsiosis and other rickettsial syndromes is increasing as a result of several factors. Most rickettsial infections can be controlled by antibiotic therapy, but prompt recognition and diagnosis of these diseases remains difficult.

Q Identify the three major categories of organisms that cause rickettsial diseases. For typhus, spotted fever

rickettsiosis, and ehrlichiosis, identify the most common reservoir and vector.

- 32.4** Lyme disease is caused by the spirochete *Borrelia burgdorferi* and is the most prevalent arthropod-borne disease in the United States today. The pathogen is transmitted from several mammalian host reservoirs to humans by tick vectors. Prevention and treatment of Lyme disease are straightforward, but accurate and timely diagnosis of infection is essential.

Q Identify the most common reservoir and vector for Lyme disease in the United States. How can the spread of Lyme disease be controlled? How can Lyme disease be treated?

- 32.5** Yellow, dengue, and Zika fevers are caused by related flaviviruses transmitted to humans by mosquito bites; Chikungunya fever shows similar disease symptoms but is caused by a togavirus. These diseases are widespread in tropical and subtropical countries and can show mild to severe symptoms, including hemorrhagic fevers. An effective vaccine for yellow fever is in use. A vaccine for dengue is in restricted use. No vaccine is currently available to prevent Zika or Chikungunya infections, but vaccines against both viruses are in development.

Q Why are people with active cases of yellow fever put in isolation?

- 32.6** West Nile fever is a mosquito-borne viral disease. In the natural cycle of the pathogen, birds are infected with West Nile virus by the bite of infected mosquitoes. Humans and other vertebrates are occasional terminal hosts. Most human infections are asymptomatic and undiagnosed, but complications of some infections cause about 5% mortality.

Q Describe the spread of West Nile virus infections in the United States. Which animals are the primary hosts? Are humans productive alternate hosts?

32.7 Plague can be transmitted to individuals who have had contact with rodent populations and their parasitic fleas, the enzootic reservoirs for the plague bacterium, *Yersinia pestis*. A systemic infection or a pneumonic infection usually leads to rapid death, but the bubonic form is treatable with antibiotics.

Q For a potentially serious disease like bubonic plague, vaccines are not routinely recommended for the general population; why not? Identify the public health measures used to control plague.

III • Soilborne Bacterial Diseases

32.8 Anthrax is caused by the endospore-forming bacterium *Bacillus anthracis* and can take on three different forms: cutaneous, intestinal, or inhalation. Cutaneous anthrax is most common and along with inhalation anthrax is an occupational hazard for livestock workers, where

B. anthracis endospores can be transmitted from animal hides to humans.

Q Which key feature of the bacterium *Bacillus anthracis* allows this organism to persist for extended periods on animal hides or other environments where growth may not occur? Which form of anthrax is the most serious?

32.9 *Clostridium tetani* is a soil bacterium that causes tetanus, a potentially fatal disease characterized by a toxemia and rigid paralysis. Treatment for acute tetanus includes antibiotics and active and passive immunization, and the disease is preventable by toxoid immunization. Gas gangrene occurs from the growth of various proteolytic clostridia in traumatic wounds, leading to gas and toxin formation.

Q Discuss the major mechanism of pathogenesis for tetanus and define measures for prevention and treatment. Why is it possible that a traumatic puncture wound could end up causing both tetanus and gas gangrene?

APPLICATION QUESTIONS

- Describe the sequence of steps you would take if your child received a bite (provoked or unprovoked) from a stray dog with no collar and record of rabies immunization. Present one scenario in which you were able to capture and detain the dog and another for a dog that escaped. How would these procedures differ from a situation in which the child was bitten by a dog that had a collar and rabies tag with documented, up-to-date rabies immunizations?
- Contrast the modes of transmission of the following diseases: rabies, Lyme disease, yellow fever, West Nile disease, anthrax, and plague. Which of these diseases could be virtually eliminated in humans by control of the disease vector and which could not, and why?
- Devise a plan to prevent the spread of West Nile virus to humans in your community. Identify the relative costs involved in such a plan, both at the individual level and at the community level. Find out if a mosquito abatement program is active in your community. What methods, if any, are used in your area for the reduction of mosquito populations? What is a simple way to limit mosquito numbers around your residence?

CHAPTER GLOSSARY

Enzootic an endemic disease present in an animal population

Epizootic an epidemic disease present in an animal population

Gas gangrene tissue destruction due to the growth of proteolytic and gas-producing clostridia

Hantavirus pulmonary syndrome (HPS) an emerging, acute disease characterized by pneumonia and caused by rodent hantavirus

Hemorrhagic fever with renal syndrome (HFRS) an emerging, acute disease characterized by shock and kidney failure and caused by rodent hantavirus

Lyme disease a tick-transmitted disease caused by the spirochete *Borrelia burgdorferi*

Plague an enzootic disease in rodents that is caused by *Yersinia pestis* and can be transferred to humans through the bite of a flea

Rabies a usually fatal (if untreated) neurological disease caused by the rabies virus, which is typically transmitted by the bite or saliva of an infected animal

Rickettsias obligate intracellular bacteria of the genus *Rickettsia* and related genera responsible for diseases including typhus, spotted fever rickettsiosis, and ehrlichiosis

Spotted fever rickettsiosis (SFR) a tick-transmitted disease caused by *Rickettsia rickettsii*, characterized by fever, headache, rash, and gastrointestinal symptoms; also called Rocky Mountain spotted fever

Tetanus a disease characterized by rigid paralysis of the voluntary muscles, caused by an exotoxin produced by *Clostridium tetani*

Typhus a louse-transmitted disease caused by *Rickettsia prowazekii*, characterized by fever, headache, weakness, rash, and damage to the central nervous system and internal organs

West Nile fever a neurological disease caused by West Nile virus, a virus transmitted by mosquitoes from birds to humans

Zoonosis any disease that occurs primarily in animals but can be transmitted to humans

Waterborne and Foodborne Bacterial and Viral Diseases

33

MICROBIOLOGYNOW

Reverse Zoonosis in the Southern Ocean

A zoonosis is an animal disease that is transmissible to humans, usually by direct contact (including bites) or airborne particles. Rabies, for example, is a classic zoonotic disease. But does the opposite ever happen? That is, do humans ever transmit pathogens to animal populations?

The answer is yes, “reverse zoonotic” transmission occurs regularly when humans and animals are in close proximity, but, with the exception of a few key pathogens (for example, influenza A), this transmission generally poses no significant threat to animal populations as a whole. But is this also true for animal species that have historically been isolated from contact with humans? Not having coevolved with humans, are these animals more at risk from novel exposures to anthropogenic opportunistic pathogens?

This question has come to the forefront in Antarctica, where vibrant multinational research programs and a burgeoning tourism industry have led to more traffic—tens of thousands of visitors every year—on and around the Southern Ocean than ever before.

Ever since centuries-old murmurings of an unseen, mythical land to the far south of the globe were confirmed in the 1820s, research scientists and adventurous travelers have found the allure of the frozen continent compelling. However, the steadily increasing presence of humans—and in particular, their gut microbiota—may negatively impact Antarctic and subantarctic animal populations.

A recent study identified human-derived enteric pathogens, including antibiotic-resistant strains of *Salmonella* and *Campylobacter* spp., in fecal samples from Antarctic marine birds such as various penguins (photo, an Adélie penguin rookery in Cape Bird, Ross Island, Antarctica), brown skuas, and gulls. Although the long-term ramifications of reverse zoonosis in Antarctica are unclear, the study shows that stricter biosecurity regulations to limit the potential for widespread reverse zoonotic outbreaks among sensitive animal populations may be a prudent and perhaps overdue course of action.

Source: Cerdà-Cuellar, M., et al. 2019. Do humans spread zoonotic enteric bacteria in Antarctica? *Sci. Total Environ.* 654: 190. doi: 10.1016/j.scitotenv.2018.10.272.

In this chapter we consider microbial pathogens whose mode of transmission is either water or food. The diseases caused by these pathogens are called “common-source” diseases because they occur only in those who have consumed the same contaminated water or eaten the same contaminated food (◀ Section 30.4). Waterborne and foodborne illnesses are common infectious diseases worldwide. While foodborne illnesses are most commonly of bacterial or viral origin, waterborne illnesses can have bacterial, viral, or parasitic causes. Waterborne diseases caused by eukaryotic pathogens will be considered in Chapter 34.

I • Water as a Disease Vehicle

Whether potable or recreational, water is a potential source of a variety of pathogenic microorganisms that can cause serious disease. Because of this, rapid and accurate methods to test water quality are essential to maintain public health standards.

Water is used in enormous quantities, and its microbiological safety rests in the hands of wastewater and drinking water engineers and microbiologists. Indeed, water quality is the single most important factor for ensuring public health. In Chapter 22 we examined the microbiology of wastewater and examined how highly polluted water can be cleaned by microbial activities and reused for many purposes, including for drinking. Here we see what can happen when water intended for human use becomes a vehicle for disease.

Waterborne diseases begin as infections (or occasionally as toxemias), and contaminated water may cause an infection even if only small numbers of the particular pathogen are present. Whether exposure causes disease or not is a function of the virulence of the pathogen and the ability of the host to resist infection.

33.1 Agents and Sources of Waterborne Diseases

Mastering
Microbiology
Art Activity:
Table 33.1 Major
waterborne
pathogens

Many different microorganisms can cause waterborne infectious diseases, and some of the major ones are summarized in Table 33.1. Many different microbes can be waterborne pathogens, but here we will consider bacterial pathogens with a major focus on cholera, a waterborne disease of pandemic proportions (◀ Section 30.8). We consider a few viral pathogens that can be either foodborne or waterborne later in this chapter.

We begin by considering the disease vehicle itself—water. Waterborne illnesses can be transmitted through untreated or improperly treated water used for drinking or food preparation or from water used for swimming and bathing (recreational water sources). The major waterborne illnesses traced to drinking water and recreational waters are typically quite different, and these different disease patterns are shown in Table 33.2.

Potable Water

Water supplies in developed countries typically meet rigid quality standards, greatly reducing the spread of waterborne diseases. Drinking water in particular undergoes extensive treatment that includes

TABLE 33.1 Major waterborne pathogens

Pathogen	Disease
Bacteria^a	
<i>Vibrio cholerae</i>	Cholera
<i>Legionella pneumophila</i>	Legionellosis
<i>Salmonella enterica</i> (typhi)	Typhoid fever
<i>Escherichia coli</i>	Gastrointestinal illness
<i>Pseudomonas aeruginosa</i>	Nosocomial pneumonia, septicemia, and skin infections
<i>Campylobacter jejuni</i>	Gastrointestinal illness
Viruses	
Norovirus	Gastrointestinal illness
Hepatitis A virus	Viral hepatitis
Parasites^b	
<i>Cryptosporidium parvum</i>	Cryptosporidiosis
<i>Giardia intestinalis</i>	Giardiasis
<i>Schistosoma</i>	Schistosomiasis

^aExcept for *S. enterica* (typhi), these bacteria have been associated with major outbreaks of waterborne illness in the United States in recent years, as have the bacteria *Shigella sonnei* and *Leptospira* sp.

^bSee Chapter 34. *C. parvum* and *G. intestinalis* are unicellular microbial parasites; *Schistosoma* is a microscopic worm 10–20 mm long (see MicrobiologyNow in the Chapter 28 opener).

both filtration and chlorination. Although filtration removes turbidity and many microorganisms, it is *chlorination* that makes drinking water safe. Chlorine gas (Cl₂) is a strong oxidant and oxidizes both organic matter dissolved in the water and microbial cells themselves. Drinking water chlorination facilities add sufficient chlorine to allow a residual level to remain in the water all the way to the consumer. Water suitable for human consumption is called **potable** water (◀ Sections 22.7–22.10).

Despite filtration and chlorination, waterborne disease outbreaks from potable water occasionally occur. In the United States an average of 40 outbreaks of disease associated with drinking water are recorded in a year (a waterborne outbreak is defined as two or more human illnesses specifically linked to the consumption of the same water at the same time). About 60% of drinking water disease outbreaks are due to *bacterial* pathogens, most notably *Legionella*, the causative agent of legionellosis (Table 33.2 and Section 33.4).

Recreational Waters

Recreational waters include freshwater aquatic systems such as ponds, streams, and lakes, as well as public swimming and wading pools. Recreational waters can be sources of waterborne disease, and on average they cause more disease outbreaks than those due to drinking water (Table 33.2). Moreover, in contrast to drinking water, where *bacterial* pathogens are most common, disease outbreaks from recreational waters are more frequently linked to *parasitic* (eukaryotic) pathogens. In addition, recreational waters transmit a significant number of gastrointestinal illnesses that are of unknown origin (Table 33.2).

In the United States, the operation of public swimming pools is regulated by state and local health departments. The United States

TABLE 33.2 Sources of outbreaks of acute gastrointestinal illness in drinking and recreational waters, 2013–2014^a

	Drinking water (n = 42) (%)	Recreational water (n = 493) (%)

^aNumbers are rounded to the nearest percent and were obtained from the Centers for Disease Control and Prevention Waterborne Disease and Outbreak Surveillance System.
^bOutbreak linked to more than one cause.
^cSuspected to be caused by one or more microbes or chemicals but not confirmed.

Environmental Protection Agency (EPA) establishes limits for bacterial numbers in both potable and public recreational water sources, but local and state governments can set standards above or below these guidelines for nonpotable sources. By contrast, the water quality of *private* recreational waters, such as swimming pools, spas, and hot tubs, is totally unregulated, and these are therefore prime vehicles for waterborne disease transmission.

Check Your Understanding

- What is potable water?
- Contrast the major pathogens responsible for disease outbreaks in drinking water versus recreational waters.

33.2 Public Health and Water Quality

Water that looks perfectly transparent may still be contaminated with pathogenic microorganisms and thus pose a risk of disease. It is impractical to screen water for every pathogen that may be present (Table 33.1), and so both potable and recreational waters are routinely tested for specific *indicator organisms*, the presence of which signals the potential for waterborne disease.

Coliforms and Water Quality

A widely used indicator for microbial water contamination is the **coliform** group of bacteria. Many coliforms inhabit the intestinal tract of humans and other animals, and therefore their presence in water indicates likely fecal contamination. Coliforms are defined as facultatively aerobic, gram-negative, rod-shaped, nonsporulating bacteria that ferment lactose with the production of gas within 48 h at 35°C. However, this definition includes several bacteria that are not necessarily restricted to the intestine; for this reason, it is *fecal coliforms* that are important in water safety assessments. *Escherichia coli*, a coliform whose only habitat is the intestine and that survives only a relatively short time outside the intestine, is the key fecal coliform of interest. The presence of cells of *E. coli* in a water sample is taken as evidence of fecal contamination and means that the water

is unsafe for human consumption. Conversely, however, the absence of *E. coli* does not ensure that a water source is potable, because other pathogenic bacteria or pathogenic viruses or protists may still be present.

Testing for Fecal Coliforms and the Importance of *Escherichia coli*

Well-developed and standardized methods are in routine use for detecting coliforms and fecal coliforms in water samples. A common method is the *membrane filter (MF)* procedure where at least 100 ml of freshly collected water is passed through a sterile membrane filter, trapping any bacteria on the filter surface. The filter is placed on a plate of eosin–methylene blue (EMB) medium, which is selective for gram-negative, lactose-utilizing bacteria. EMB medium is also differential, allowing strongly fermentative species such as *E. coli* (Figure 33.1a) to be distinguished from weakly fermentative species such as *Proteus*.

Selective media are also available that not only detect total coliforms but also specifically identify *E. coli* simultaneously. These *defined substrate tests* are typically faster and more accurate than EMB-based assays. One popular plate-based test is based on the ability of *E. coli* but not other enteric bacteria to metabolize a combination of two specific chemicals to form a fluorescent blue compound (Figure 33.1b). A commonly used liquid method reveals whether coliforms are present and also specifically detects *E. coli* in the water sample (Figure 33.1c). In addition to these colorimetric tests, dipstick assays have been developed that detect adenosine triphosphate (ATP) in a water sample. There is a strong correlation between the total number of bacteria in a sample and its ATP content, and the latter can be measured using the luciferase enzyme system in which a flash of light is emitted when ATP is hydrolyzed (◀ Figure 10.4b). Using this system, the total microbial load in a water sample can be quickly assessed, and portable kits are available commercially to carry out these analyses in water purification facilities as well as remote field sites.

Reporting Water Purity Data

In properly regulated drinking water supply systems, total coliform and *E. coli* fecal coliform tests should be negative. A positive test indicates that a breakdown has occurred in either the purification or distribution system (or both). In the United States, microbiological standards for drinking water are specified in the *Safe Drinking Water Act* and are administered by the Environmental Protection Agency (EPA). Water utilities must report coliform test results to the EPA monthly, and if they do not meet the prescribed standards, the utilities must notify the public and take steps to correct the problem.

Major improvements in public health in the United States beginning in the early twentieth century were largely due to the adoption of water filtration and chlorination procedures in large-scale wastewater and drinking water treatment plants (◀ Sections 22.8 and 22.9). Where drinking water standards have not reached this level, especially in developing countries, a variety of waterborne diseases are common. We turn our attention to these diseases now, beginning with cholera, the most widespread and devastating of all waterborne diseases.

Figure 33.1 Fecal coliforms and their detection in water samples. (a) Colonies growing on a membrane filter. A drinking water sample was passed through the filter and the filter placed on an eosin-methylene blue (EMB) agar plate (EMB is both selective and differential for coliforms; more strongly fermentative species [such as *Escherichia coli*] form colonies with darker centers). (b) Total coliforms and *E. coli*. A filter ex-

posed to a drinking water sample was incubated at 35°C for 24 hours on a medium containing special compounds that fluoresce when metabolized. The filter was then examined under ultraviolet light. The single *E. coli* colony in the sample fluoresces dark blue (arrow). Coliforms that do not metabolize the compound form colonies that fluoresce white to light blue. (c) The IDEXX Colilert® water quality test system.

When specific reagents are added to water samples and incubated for 24 h, they develop a yellow color if they contain coliforms (right). Samples containing *Escherichia coli* develop a yellow color but also fluoresce blue (left). Samples negative for coliforms remain clear (center).

Check Your Understanding

- Why is *Escherichia coli* used as an indicator organism in microbial analyses of water?
- What procedures are used to ensure the safety of potable water supplies?

II • Waterborne Diseases

Waterborne diseases can result from ingestion of contaminated water, causing serious gastrointestinal distress, or inhalation of contaminated aerosols, causing respiratory illness and pneumonia-like symptoms. Cholera is a prime example of a dangerous waterborne disease.

Waterborne infectious diseases are a constant threat to humanity, especially in areas where proper sanitation and supplies of potable drinking water are either unavailable or subject to intermittent disruption. Cholera leads the list here for its potential to initiate large-scale and rapidly developing disease outbreaks.

33.3 *Vibrio cholerae* and Cholera

Cholera is a severe gastrointestinal diarrheal disease that is now largely restricted to countries in the developing world. Cholera is caused by ingestion of contaminated water containing cells of *Vibrio cholerae*, a gram-negative and motile curved species of *Proteobacteria* (Figure 33.2). Cholera can also be contracted from contaminated food, especially improperly cooked shellfish.

The ingestion of a large number ($> 10^8$) of *V. cholerae* cells is required to cause disease. The ingested cells attach to epithelial cells in the small intestine where they grow and release *cholera toxin*, a

potent enterotoxin (◀ Figure 25.16). Studies with human volunteers have shown that normal stomach acidity (about pH 2) is why the large inoculum of *V. cholerae* cells is needed to initiate disease. In these studies, those given bicarbonate to neutralize gastric acidity develop cholera when given as few as 10^4 cells. Even lower cell numbers can initiate infection if *V. cholerae* is ingested with food, presumably because the food protects the vibrios from destruction by stomach acidity.

Cholera enterotoxin causes severe diarrhea that can rapidly result in dehydration and death unless the patient is given fluid and electrolyte therapy. The enterotoxin causes fluid losses of up to 20 liters (20 kg or 44 lb) per person per day, causing severe dehydration. The mortality rate from *untreated* cholera is 25–50% and can be even higher under conditions of severe crowding and malnutrition as often occurs in refugee camps or in areas that have experienced natural disasters, such as floods and earthquakes. In these situations, there is often a near-complete breakdown in sanitation, leading to the contamination of drinking water with feces and the rapid transmission of cholera.

Diagnosis, Treatment, and Prevention of Cholera

At treatment facilities in large outbreaks of cholera, each cholera patient is placed on a “cholera cot,” which is a conventional folding cot containing an opening into which feces can be voided (Figure 33.2). The feces of a cholera patient are more liquid than solid, and confirmation of the disease is straightforward because the pathogen is easily cultured on selective agar media (Figure 33.2). Cholera treatment is simple and effective. An oral (or in severe cases, intravenous) liquid and electrolyte replacement therapy is the most effective means of treatment. Oral treatment is preferred because no special equipment or sterile precautions are necessary.

The rehydration solution is a mixture of glucose, salt (NaCl), sodium bicarbonate (NaHCO_3), and potassium chloride (KCl). If the solution is administered quickly during an outbreak, cholera mortality can be greatly reduced, as rehydration allows patients the time necessary to mount an immune response.

Antibiotics may shorten the course of cholera infection and the shedding of viable cells, but antibiotics are of little health benefit to

the patient without simultaneous fluid and electrolyte replacement. Public health measures such as adequate sewage treatment and a reliable source of safe drinking water are the keys to preventing cholera. *V. cholerae* is eliminated from wastewater during proper sewage treatment and drinking water purification procedures (Chapter 22). For individuals traveling in cholera-endemic areas, attention to personal hygiene and avoidance of untreated water or ice, raw food,

Figure 33.2 Infection cycle, symptoms, and diagnosis of cholera. Highly motile cells of *Vibrio cholerae*, the causative agent of cholera (upper left, scanning electron micrograph, note flagella), may associate with algae in freshwaters (lower left) in cholera endemic areas and be inadvertently ingested by a human host. Subsequent colonization of the small intestine and enterotoxin secretion by *V. cholerae* (◀ Figure 25.16)

causes severe diarrhea in the form of “rice water” stools, so called because they are extremely watery and contain flecks of whitish-colored mucus. While being treated for cholera, patients lie prostrate on “cholera cots” and void feces directly into a bucket below (top right). Any contamination of natural waters by patient stools (for example, by emptying or rinsing cholera buckets in local streams) magnifies and

Symptoms and diagnosis

prolongs the cholera outbreak. Patient diagnosis is confirmed by recovering cells of *V. cholerae* from a stool sample using selective culture media, such as medium TCBS (middle right), which contains bile salts and citrate to inhibit enterobacteria and gram-positive bacteria, as well as thiosulfate and sucrose, which cells of *V. cholerae* (bottom right) use as a sulfur and carbon/energy source, respectively.

and raw or undercooked fish or shellfish that can feed on phytoplankton contaminated with *V. cholerae* (Figure 33.2) can prevent cholera.

Since 1817, cholera has swept the world in seven major pandemics with an eighth pandemic likely already started (◀ Section 30.8 and Figure 30.15). The World Health Organization estimates that only 5–10% of cholera cases are reported, so the total worldwide incidence of cholera probably exceeds 1 million cases per year. Only a handful of cases of cholera are reported each year in the United States, typically from imported shellfish that are eaten raw or after only minimal cooking.

33.4 Legionellosis

Legionella pneumophila, the bacterium that causes *legionellosis*, is an important waterborne pathogen whose transmission was originally linked to aerosols from evaporative cooling devices. However, *L. pneumophila* (Figure 33.3) is now known to be a major pathogen in residential water systems as well, where the organism persists in biofilms that form on interior surfaces of water distribution pipes and also within the cells of certain microbial parasites. In these sites, *L. pneumophila* is protected from the chlorine present in potable waters, and thus biofilms and infected parasites are reservoirs for transmitting legionellosis by a waterborne route (◀ Section 22.10 and Figure 22.25).

Pathogenesis, Diagnosis, and Treatment

Cells of *L. pneumophila* invade the lungs and grow within macrophages and monocytes. Infections are often asymptomatic or produce only a mild cough, sore throat, mild headache, and fever; these self-limiting cases typically resolve themselves in 2–5 days. However, the elderly, whose resistance may be naturally reduced, and those with compromised immune systems often acquire more serious *Legionella* infections resulting in pneumonia. Prior to the onset of pneumonia, intestinal disorders, followed by high fever, chills, and muscle aches, are common. These symptoms precede the dry cough and chest and abdominal pains typical of legionellosis. Up to 10% of cases that reach this stage are fatal, usually as a result of respiratory failure.

Clinical detection of *L. pneumophila* infection is usually done by culture of the organism from bronchial washings, pleural fluid, or other body fluids or tissues (Figure 33.3d). Various serological tests can detect anti-*Legionella* antibodies or *Legionella* cells in these samples and also from patient urine, and this is used to confirm a diagnosis (Figure 33.3b). Legionellosis can be treated with antibiotics, in particular rifampin and erythromycin, and intravenous administration of erythromycin is the treatment of choice for life-threatening cases.

Figure 33.3 *Legionella pneumophila*. (a) Gram-stained cells of *L. pneumophila* from lung tissue of a legionellosis victim. (b) Cells of *L. pneumophila* can be positively identified using fluorescent anti-*L. pneumophila* antibodies (◀ Section 29.6). (c) Colorized scanning electron micrograph of *L. pneumophila* cells. Cells are about $0.5 \times 2 \mu\text{m}$. (d) Colonies of *L. pneumophila* grown on a complex enrichment medium showing their typical textured surface.

Epidemiology

L. pneumophila is a gram-negative, obligately aerobic rod-shaped species of the *Gammaproteobacteria* (Figure 33.3) and shows complex nutritional requirements, including an unusually high requirement for iron. The organism can be isolated from terrestrial and aquatic habitats as well as from legionellosis patients. *Legionella pneumophila* was first recognized as the pathogen that caused an outbreak of fatal pneumonia at an American Legion convention (thus the name legionellosis) in Philadelphia (USA) in 1976. Besides legionellosis, the same bacterium can also cause a milder syndrome called *Pontiac fever*.

L. pneumophila is present in freshwaters and in soil. It is relatively resistant to heating and chlorination, so it can spread through drinking water distribution systems (◀ Section 22.10). The pathogen is often found in large numbers in improperly sanitized cooling towers and evaporative condensers of large air conditioning systems. The pathogen grows in the water and is disseminated in humidified aerosols. Human infection is by way of airborne droplets, but the infection does not spread from person to person.

Besides its presence in evaporative coolers and domestic water systems, *L. pneumophila* has also been detected in hot water tanks and spas; in the latter, it can reach high cell numbers in warm (35–45°C), stagnant water, especially if chlorine (or other sanitizer) levels are not maintained. Many outbreaks of legionellosis have been linked to swimming pools. *L. pneumophila* can be eliminated from water supplies by hyperchlorination or by heating water to greater than 63°C. Although incidence peaks in the summer months, epidemiological studies indicate that *L. pneumophila* infections can occur at any time of year, primarily as a result of aerosols generated from heating and cooling systems and contaminated premise water.

(◀ Section 22.10) used for showering or bathing. In the United States, a few thousand cases of legionellosis are typically reported each year.

33.5 Typhoid Fever and Norovirus Illness

Although cholera and legionellosis are among the more lethal waterborne diseases, other waterborne pathogens also cause serious disease. We focus on two major ones here, the causative agents of typhoid (a bacterium) and norovirus gastrointestinal illness (an RNA virus).

Typhoid Fever

On a global scale, probably the most important waterborne bacterial pathogens are *Vibrio cholerae* (Section 33.3) and *Salmonella enterica* (*typhi*), the organism that causes typhoid fever. *S. enterica* (*typhi*) is a gram-negative, peritrichously flagellated bacterium related to *Escherichia coli* and other enteric bacteria (Figure 33.4a). The organism is transmitted in feces-contaminated water, and thus typhoid fever, like cholera, is primarily restricted to areas where sewage treatment and general sanitation are either absent or poorly maintained. Typhoid today is a well-entrenched endemic disease in sub-Saharan Africa, the Indian subcontinent, and Indonesia, but appears only sporadically in North America, Europe, northern Asia, and Australia.

Typhoid fever progresses in several stages. Cells of the pathogen (Figure 33.4a) ingested in contaminated water (or occasionally food) reach the small intestine where they grow and enter the lymphatic system and the bloodstream; from here, the pathogen can travel to many different organs. One to two weeks later, the first symptoms of typhoid appear and include a mild fever, headache, and general malaise. During this period, the liver and spleen of the typhoid patient become heavily infected. About a week later, the

fever becomes more intense (up to 40°C), and the patient typically becomes delirious; diarrhea can occur in this stage and abdominal pain can be severe. Complications can follow, including intestinal bleeding and perforation of the small intestine. The latter releases large numbers of bacterial cells into the abdomen, leading to a condition called *sepsis* (systemic infection and inflammation) and possibly also to septic shock. Both of these conditions are potentially fatal, and up to 40% of sepsis cases are fatal. After about a week in this crisis stage, the symptoms of typhoid begin to diminish, and recovery occurs.

Treatment for typhoid consists of antibiotic therapy and fluid replacement to ward off dehydration. In some cases, surgery may be necessary to repair perforated intestines. Although a variety of antibiotics can kill *S. enterica* (*typhi*), resistance to many of these has developed. Isolation of the causative strain and assessment of its antibiotic sensitivity (◀ Section 29.4) is often necessary to ensure that antibiotics will cure the infection.

In the United States, fewer than 400 cases of typhoid occur per year, but typhoid fever used to be a major public health threat before drinking water was routinely filtered and chlorinated (◀ Figure 30.7). However, breakdown of water treatment methods, contamination of water during floods, earthquakes, and other disasters, or contamination of water supply pipes with leakage from sewer lines can propagate epidemics of typhoid fever, even in developed countries.

In some typhoid patients, the gallbladder becomes infected with the pathogen. If these individuals also have gallstones, these can become colonized with *S. enterica* (*typhi*) cells and serve as a long-term reservoir of the pathogen from which it is continuously shed into feces and urine. Such individuals are otherwise healthy “carriers” of typhoid and can transmit the disease over long periods. The notorious “Typhoid Mary,” who as a cook for hire spread typhoid throughout the New York City area for nearly 15 years beginning in the early twentieth century, was the classic example of a typhoid carrier.

Norovirus Illness

Viruses can be transmitted in water and cause human disease. Norovirus (Figure 33.4b) is one example and a common cause of gastrointestinal illness due to contaminated water (or food, Section 33.14). Norovirus is a single-stranded plus-sense RNA virus (◀ Section 11.8) and is the leading cause of gastrointestinal illnesses worldwide (see Table 33.5). The virus specifically attacks *tuft cells* found in the intestinal epithelium. Normally quite rare, tuft cells proliferate during parasitic worm infections, and this likely explains why parasite-infected mice, having more tuft cells, experience more severe symptoms from exposure to norovirus than mice that do not have a worm infection. Presumably, humans would show similar responses to these infections.

Norovirus infection causes symptoms of vomiting, diarrhea, and malaise of relatively short duration. The disease is rarely fatal, although in compromised individuals (very young, elderly, or immune deficient), the significant dehydration that accompanies repeated bouts of norovirus-triggered vomiting and diarrhea can be life-threatening. A clinical diagnosis of norovirus gastrointestinal illness is made by a combination of observing symptoms and the direct

Figure 33.4 Bacterial and viral agents of severe gastrointestinal waterborne diseases. (a) Flagella-stained cells of *Salmonella enterica* (*typhi*) showing peritrichous flagellation (◀ Section 2.9). A single cell measures about $1 \times 2 \mu\text{m}$. (b) Transmission electron micrograph of virions of norovirus. A single virion is about 30 nm in diameter.

detection of either viral RNA by RT-PCR (◀ Sections 12.1 and 29.8) or viral antigens by enzyme immunoassay (◀ Section 29.7) in samples of feces or vomit.

Norovirus disease is easily transmitted person to person or to food by the fecal–oral route. The infectious dose is very small, as exposure to as few as 10–20 norovirus virions (Figure 33.4*b*) is sufficient to initiate disease. The most common sources of waterborne norovirus outbreaks are well water or recreational waters that have been contaminated with sewage. Norovirus is also often the culprit when mass common-source gastrointestinal illnesses strike people on cruise ships or in long-term care facilities or other group settings. In these situations, the virus can be transmitted person to person, by contaminated food or water (usually food, such as shellfish, deli meats, and fruits and vegetables), or by any combination of these.

Mastering
Microbiology

Art Activity:
Table 33.3
Microbial
spoilage of
fresh food

By their very nature, foods are nutritious substances. Proper food storage and preservation practices are thus necessary to prevent food contamination and common-source foodborne outbreaks.

The foods we eat, whether they are fresh, prepared, or preserved, are rarely sterile. Instead, they are almost always contaminated with spoilage microorganisms of various kinds and occasionally with pathogens. Microbial activities are key to the production of some foods, such as fermented foods, but most of the microorganisms in or on food are unwelcome and diminish either food quality or safety (or both). In the next two sections, we explore the contrasting processes of food spoilage and food preservation, how food safety is assessed, and the transmission of pathogens in food. In the remainder of the chapter we focus on major foodborne diseases.

33.6 Food Spoilage and Food Preservation

Many foods provide an excellent medium for the growth of bacteria and fungi. Properly stored food can still undergo food spoilage but is usually not a vehicle for disease, assuming that it was free of pathogens to begin with. This is because with rare exception, organisms responsible for food spoilage are not the same as those that cause foodborne illnesses.

Food Spoilage

Food spoilage is any change in the appearance, smell, or taste of a food product that makes it unacceptable to the consumer, regardless of whether the change is due to microbial growth. Foods are rich in organic matter, and the physical and chemical characteristics of a food determine its susceptibility to microbial activity. With respect to spoilage, a food or food product falls into one of three categories:

(1) **Perishable foods** include many fresh food items such as meats and many fruits and vegetables; (2) **semiperishable foods** include foods such as potatoes, some apples, and nuts; and (3) **nonperishable foods** include items such as sugar and flour. The foods in these categories differ primarily with regard to their *moisture content*, as measured by their water activity (a_w , ▶ Section 4.15). Nonperishable foods have low moisture levels and can generally be stored for long periods without spoilage. Perishable and semiperishable foods, by contrast, typically have higher moisture levels and hence these foods must be stored under conditions that inhibit microbial growth.

Fresh foods are typically spoiled by a wide variety of bacteria and fungi (Table 33.3). The chemical properties of foods vary widely, and each food is characterized by its moisture level and the nutrients it contains as well as other factors, such as its acidity or alkalinity. As a result, each susceptible food is typically spoiled by a specific group of microorganisms. The time required for a microbial population to reach a significant level in a given food product depends on both the size of the initial inoculum and the rate of growth during the exponential phase. Microbial numbers in a food product may initially be so low that no measurable effect can be observed, with only the last few cell doublings leading to observable spoilage. Hence, an unconsumed portion of a food product that is palatable and eaten one day can be badly spoiled the next.

The type of food spoilage and the microbial composition of the spoilage community (Table 33.3) are functions of both the food product and the storage temperature. Food spoilage microorganisms

TABLE 33.3 Microbial spoilage of fresh food^a

Food product	Type of microorganism	Common spoilage organisms, by genus
Fruits and vegetables	Bacteria	<i>Erwinia</i> , <i>Pseudomonas</i> , <i>Corynebacterium</i> (mainly vegetable pathogens; rarely spoil fruit)
	Fungi	<i>Aspergillus</i> , <i>Botrytis</i> , <i>Geotrichum</i> , <i>Rhizopus</i> , <i>Penicillium</i> , <i>Cladosporium</i> , <i>Alternaria</i> , <i>Phytophthora</i> , various yeasts
Fresh meat, poultry, eggs, and seafood	Bacteria	<i>Acinetobacter</i> , <i>Aeromonas</i> , <i>Pseudomonas</i> , <i>Micrococcus</i> , <i>Achromobacter</i> , <i>Flavobacterium</i> , <i>Proteus</i> , <i>Salmonella</i> , <i>Escherichia</i> , <i>Campylobacter</i> , <i>Listeria</i>
	Fungi	<i>Cladosporium</i> , <i>Mucor</i> , <i>Rhizopus</i> , <i>Penicillium</i> , <i>Geotrichum</i> , <i>Sporotrichum</i> , <i>Candida</i> , <i>Torula</i> , <i>Rhodotorula</i>
Milk	Bacteria	<i>Streptococcus</i> , <i>Leuconostoc</i> , <i>Lactococcus</i> , <i>Lactobacillus</i> , <i>Pseudomonas</i> , <i>Proteus</i>
High-sugar foods	Bacteria	<i>Clostridium</i> , <i>Bacillus</i> , <i>Flavobacterium</i>
	Fungi	<i>Saccharomyces</i> , <i>Torula</i> , <i>Penicillium</i>

^aThe organisms listed are the most commonly observed spoilage agents of fresh, perishable foods. Many of these genera include species that are human pathogens (Chapters 31–34).

are often *psychrotolerant*, meaning that although they grow best at temperatures above 20°C, they can also grow at refrigeration temperatures (3–5°C) (◀ Section 4.12). However, at any given storage temperature, some species grow faster than others, and thus the composition of the microbial spoilage community of the same food product stored at different temperatures can vary significantly.

Food Preservation and Fermentation

Food storage and preservation methods are designed to slow or stop the growth of microorganisms that spoil food or that can cause foodborne disease. The major methods of food preservation include altering the temperature, acidity, or moisture level of the food, or treating it with radiation or chemicals that prevent microbial growth.

Refrigeration slows microbial growth, but a remarkable number of microorganisms, particularly bacteria, can grow at refrigeration temperatures. Storage of foods in a freezer reduces growth considerably, but slow growth still occurs in pockets of liquid water trapped within the frozen food. In general, a lower storage temperature results in less microbial growth and slower spoilage, but storage at temperatures below –20°C is too expensive for routine use and also can negatively affect food appearance, consistency, and taste.

Heat reduces the bacterial load and can even sterilize a food product, and it is especially useful for the preservation of liquids or high-moisture foods. The limited heat treatment of **pasteurization** (◀ Section 4.17) does not sterilize liquids but reduces microbial numbers and eliminates pathogens. *Canning*, by contrast, typically sterilizes the food but requires careful processing in a sealed container at the correct temperature for the correct length of time. If viable microorganisms remain in a can or glass jar, their growth can produce gas, causing the vessel to bulge or even explode (Figure 33.5). The environment inside a can or sealed jar is anoxic, and an important genus of anaerobic bacteria that can grow in canned foods is the endospore-forming *Clostridium*, one species of which causes botulism (Section 33.9 and ▶ Section 25.6).

Foods can be made drier by either physically removing the water or by adding solutes, such as salt or sugar. Extremely dry or solute-loaded foods help prevent bacterial growth, but spoilage can still

occur and when it does, it is typically from fungi. Many foods are preserved by the addition of small amounts of antimicrobial chemicals. These chemicals, which include nitrites, sulfites, propionate, and benzoate along with a few others, find wide application in the food industry for enhancing or preserving food texture, color, freshness, or flavor. However, one of these flavor-enhancing additives, the sugar trehalose, stimulates the growth of *Clostridioides difficile*, a dangerous emerging pathogen (▶ Section 30.7). Therefore, the benefit of any chemical food additive must be weighed against its potential to cause more harm than good by inadvertently promoting the growth of unwanted microorganisms.

Perhaps the fastest growing form of food preservation is *irradiation* with ionizing radiation, especially that generated by electron beam (eBeam) technology. The application of eBeam irradiation to foods causes the oxidation—and therefore deactivation—of key macromolecules in microbial cells. Such treatment has been shown to be an effective means for reducing microbial contamination of foods without adding anything to the product itself and potentially changing its form or flavor.

Many common foods and beverages are preserved through the metabolic activities of microorganisms; these are *fermented foods* (Figure 33.6, Table 33.4, and ▶ Figure 1.16). The fermentation process (Chapters 3 and 14) yields large amounts of natural preservative chemicals. The major bacteria important in the fermented foods industry produce organic acids or fatty acids; prime examples are the lactic acid bacteria (in fermented milk products), the acetic acid bacteria (in pickling), and the propionic acid bacteria (in certain cheeses) (Table 33.4). The yeast *Saccharomyces cerevisiae* produces alcohol as the preservative in the production of alcoholic beverages.

The high level of organic acids or alcohol generated from these fermentations prevents the growth of both spoilage organisms and pathogens in the fermented food product. But the fermentation process yields more than just preservatives. Depending on the product and the microbes that carry out the fermentation, many other chemicals are released that add to the overall nutritional value, taste, and aroma of a given fermented food.

- List some dairy, meat, beverage, and vegetable foods produced by microbial fermentation. What is the preservative in each case?

33.7 Foodborne Diseases and Food Epidemiology

Foodborne illnesses resemble waterborne illnesses in being *common-source* diseases (◀Section 30.4). Most foodborne disease outbreaks are due to improper food handling and preparation by domestic consumers; these typically affect only a few people and are rarely reported. However, occasional disease outbreaks due to breakdowns in safe food handling and preparation at restaurants or food-processing and distribution plants can affect large numbers of people in geographically widespread regions.

Foodborne Diseases and Microbial Sampling

Foodborne diseases are of two types: *food infections* and *food poisonings*; some foodborne diseases fall into both categories. **Food poisoning**, also called **food intoxication**, results from ingestion of foods containing preformed microbial toxins. The microorganisms that produced the toxins do not have to grow in the host and may not even be alive at the time the contaminated food is consumed; ingestion and activity of the toxin is what causes the illness. We previously discussed some of these toxins, notably the exotoxin of *Clostridium botulinum* and the superantigen toxins of *Staphylococcus* and *Streptococcus* (◀Sections 25.6 and 28.2). In contrast to food poisoning, **food infection** occurs from the ingestion of food containing sufficient numbers of viable pathogens to cause colonization and growth of the pathogen in the host, ultimately resulting in disease.

Food infections are the most common foodborne illnesses in the United States and account for four of the top five leading foodborne illnesses. Table 33.5 lists the major microorganisms that cause food infections and food poisonings in the United States.

Eight microorganisms account for the great majority of foodborne illness, hospitalizations, and deaths in the United States: *Salmonella* species, *Clostridium perfringens*, *Campylobacter jejuni*, *Staphylococcus aureus*, *Listeria monocytogenes*, and *Escherichia coli* (all bacteria); norovirus; and *Toxoplasma* (a protist) (Table 33.5). Four of these—norovirus, *Salmonella*, *C. perfringens*, and *Campylobacter*—account for nearly 90% of all foodborne illness, with norovirus (Sections 33.5 and 33.14) being the most common culprit (60%).

Rapid diagnostic methods that do not require culturing an organism have been developed to detect important food pathogens, and many of these were described in Chapter 29. Isolation of pathogens from foods usually requires preliminary treatment of the food to suspend microorganisms embedded or entrapped within. A standard method for this purpose employs a blender called a paddle blender, or Stomacher® (Figure 33.7), a device to process food samples sealed in sterile bags. Paddles in the Stomacher crush, blend, and homogenize the samples in a fashion resembling the peristaltic action of the stomach but under conditions that prevent contamination. The homogenized samples are then analyzed for specific pathogens or their products.

In addition to identifying pathogens in the food itself, disease investigators must also recover the foodborne pathogen from the diseased patient in order to establish a cause-and-effect relationship between the pathogen and the illness. In fact, identification of the *same strain* (not just the *same species*) of a particular pathogen in patients and the suspected contaminated food is the “gold standard” for linking cause and effect in a foodborne disease outbreak, and a variety of microbiological, immunological, and molecular techniques are available for these purposes (Chapter 29).

Foodborne Disease Epidemiology

An outbreak of foodborne disease can occur in a home, a school cafeteria, a college dining hall, a restaurant, a military mess hall, or anywhere a contaminated food is consumed by many individuals. In addition, central food-processing plants and distribution centers provide opportunities for contaminated foods to cause disease outbreaks far from where the food was originally processed. It is the job

of the food epidemiologist to track disease outbreaks and determine their source, often down to the precise location in which the food was contaminated.

A good example of effective foodborne disease tracking is the outbreak caused by *Escherichia coli* O157:H7 (see Section 33.11 and Figure 33.12b) in the United States in 2006. Through culturing and molecular studies, this outbreak was linked to the consumption of contaminated packaged spinach and was quickly traced to a food-processing facility in California. The contaminated spinach was distributed nationwide from the California plant, but most disease cases were in the Midwest. In the summer of 2013, another “packaged” outbreak occurred in the Midwest but in this case was linked to lettuce instead of spinach and to the parasite *Cyclospora cayetanensis* (Section 34.4) instead of to the bacterium *E. coli*.

Figure 33.7 A paddle blender (Stomacher®). Paddles in this specialized blender homogenize the food sample contained in a sealed and sterile bag (arrow) to mimic the peristaltic action of the human stomach. The sample is first suspended in a sterile solution to form a uniform mixture.

To be effective, foodborne disease trackers must work quickly. For example, when the first case in the *E. coli* spinach outbreak appeared in late August, a link to the specific spinach product was made less than a month later. Because *E. coli* O157:H7 has been well studied, public health officials were able to quickly identify the strain contaminating the bagged spinach. Authorities then traced this strain back to the processing plant and eventually identified a specific agricultural field near the processing plant as the source of the pathogen. Although it remains unclear how the spinach was contaminated, domestic animal manure was the likely source. During the outbreak, two foodborne disease surveillance networks, *FoodNet* (Centers for Disease Control and Prevention) and *PulseNet* (an international molecular typing network for foodborne diseases), played important roles in exposing and ending the outbreak.

The spinach *E. coli* epidemic, although serious and even deadly for some, was discovered, contained, and stopped very quickly. However, this incident shows how centralized food-processing facilities can quickly spread disease to distant populations. Because of this, food hygiene standards and surveillance must be maintained at the highest possible level at all times in restaurants and central food-processing and distribution facilities.

Check Your Understanding

- Distinguish between food infection and food poisoning.

- Describe how a foodborne disease outbreak is tracked.

IV • Food Poisoning

Food poisoning occurs from the ingestion of food contaminated by bacterial or fungal toxins and does not require the producing organism to grow in the host. Food poisoning symptoms range from short-duration, mild or severe afflictions to life-threatening conditions that can be fatal.

Food poisoning can be caused by various bacteria and a few fungi. Here we consider the gram-positive bacteria *Staphylococcus aureus*, *Clostridium botulinum*, and *Clostridium perfringens*, the most common causes of bacterial food poisoning. Two of these microbes—*S. aureus* and *C. perfringens*—are among the “top five” causes of foodborne illness (Table 33.5).

33.8 Staphylococcal Food Poisoning

A powerful form of food poisoning is caused by enterotoxins (◀ Section 25.6) produced by the gram-positive bacterium *Staphylococcus aureus* (Figure 33.8; ▶ Section 16.7). This organism is commonly associated with the skin and upper respiratory tract and is a frequent cause of pus-forming wounds (▶ Section 31.9 and Figure 31.29). *S. aureus* can grow aerobically or anaerobically in many common foods and produces a suite of enterotoxins. When consumed, the toxins cause gastrointestinal symptoms characterized by one or more of nausea, vomiting, diarrhea, and dehydration. The onset of symptoms is rapid, within 1–6 h of ingestion depending on the amount of enterotoxin consumed, but the symptoms usually pass within 48 h.

Staphylococcal Enterotoxins

Many *S. aureus* enterotoxins are heat-stable and all are stable to stomach acidity. Most strains of *S. aureus* produce only one or two of these toxins, and some strains are nonproducers. However, any one of the staphylococcal (“staph”) enterotoxins can cause food poisoning. The toxins pass through the stomach to the small intestine and trigger disease symptoms from there. Besides their normal gastrointestinal activities, staph enterotoxins are also *superantigens* and can lead to potentially lethal toxic shock syndrome (▶ Sections 25.7 and 28.2).

S. aureus enterotoxins are given acronyms beginning with “SE” (for “staphylococcus enterotoxin”): SEA, SEB, SEC, and SED, which

are encoded by the genes *sea*, *seb*, *sec*, and *sed*. Not all of these genes are on the *S. aureus* chromosome, but their sequences show them to be highly related. The genes *seb* and *sec* are encoded on the bacterial chromosome, *sea* on a lysogenic bacteriophage (▶ Section 5.6), and *sed* on a plasmid. The phage- and plasmid-encoded genes can transfer the ability to make toxin to nontoxigenic strains of *Staphylococcus* by horizontal gene transfer (Chapter 9). SEA is the most common cause of staph food poisoning worldwide.

Disease Properties, Treatment, and Prevention

Foods may contain cells of *S. aureus* for several reasons. The organism may have been present on the food source itself, for example, on a meat product. More commonly, however, cells of *S. aureus* are introduced to the food by contamination from the food preparer or by contamination of the food product with raw meat or a contaminated sauce or dressing. A common scenario for a staph food poisoning incident is when a food preparer introduces *S. aureus* from nasal secretions or from an uncovered skin wound or leaking bandage into the food during its preparation. If the contaminated food is then stored at room temperature or above, the stage is set for the rapid growth of *S. aureus* and the production of staph enterotoxins.

Each year there are an estimated nearly quarter million cases of staphylococcal food poisoning in the United States. The foods most commonly implicated are custard- and cream-filled baked goods, poultry, eggs, raw and processed meat, puddings, and creamy salad dressings. Salads prepared with mayonnaise-based dressings or those that contain shellfish, chicken, pasta, tuna, potato, egg, or meat, are also common vehicles. Salted foods such as ham can be vehicles because of the ability of *S. aureus* to grow quickly in salty environments (▶ Section 31.9). If any of these foods are contaminated with *S. aureus* but are refrigerated immediately after preparation, they usually remain safe because the organism grows poorly at low temperatures. But if enterotoxin has already been produced, mild heating may not make the food safe, as staph enterotoxins are stable to 60°C.

Treatment of staph food poisoning with antibiotics is not useful because any ingested cells of *S. aureus* have already been killed by the acidity in the stomach and antibiotics have no effect on the enterotoxins. Rest, drinking plenty of fluids, and using anti-nausea drugs are the best prescription for a rapid recovery. As for any foodborne illness, staphylococcal food poisoning can be prevented by proper sanitation and hygiene in food production, preparation, and storage. In this regard, food preparers should practice thorough and frequent hand washing, prevent foods from coming into contact with nasal tissues and secretions, and routinely wear and frequently change disposable gloves when handling food products, especially if they have a bandaged hand wound.

In addition, thorough cleaning of plastic (polyethylene) cutting boards is essential but notoriously difficult, as the scratches and cuts that accumulate on these items tend to harbor significant numbers of microbes. Unlike wooden cutting boards, whose fibers tend to self-seal, and glass and granite boards that are not scored by cutting utensils, plastic cutting boards that retain deep cuts and scratches may be nearly impossible to clean satisfactorily. Despite this, these items are still used routinely in the food industry, even though the

United States Food and Drug Agency Food Code dictates that food preparation surfaces must be smooth to ensure that sanitation protocols are effective.

33.9 Clostridial Food Poisoning

The endospore-forming anaerobic bacteria *Clostridium perfringens* and *Clostridium botulinum* (◀ Section 16.8) cause serious food poisoning. Canning and cooking procedures kill vegetative cells of these species but may not kill all endospores. If this occurs, viable endospores in the food can germinate, and the resulting cells produce toxins.

There is a clear distinction in the disease process between perfringens food poisoning and botulism. In the case of botulism, the toxin is a neurotoxin and only the toxin is required for disease. Botulism does not require the growth of *C. botulinum* in the human body, but growth may nevertheless occur, particularly in cases of infant botulism. By contrast, with perfringens food poisoning, a large number of cells must be ingested in order for the toxin—in this case, an enterotoxin—to be produced.

Clostridium perfringens Food Poisoning

Clostridium perfringens (Figure 33.9a) is commonly found in soil but can also be found in sewage, primarily because it lives in small numbers in the intestinal tract of humans and other animals. *C. perfringens* is the fourth most often reported cause of foodborne disease in the United States behind norovirus illnesses (Sections 33.5 and 33.14), *Campylobacter* infections (Section 33.12), and *Salmonella* infections (Section 33.10 and Table 33.5). About 1 million cases of perfringens food poisoning occur in the United States every year.

C. perfringens is a proteolytic bacterium; proteins are catabolized by fermentation (◀ Section 14.19). Perfringens food poisoning requires the ingestion of a large dose ($>10^8$) of *C. perfringens* cells in contaminated cooked or uncooked foods, especially high-protein foods such as meat, poultry, and fish. *C. perfringens* can grow in meat

dishes cooked in bulk where heat penetration is often insufficient. *C. perfringens* grows quickly in the food, especially if left to cool at room temperature. It is when endospore formation (◀ Section 2.8 and Figures 2.26–2.29) begins that the perfringens enterotoxin is produced. The toxin alters the permeability of the intestinal epithelium, leading to nausea, diarrhea, and intestinal cramps. The onset of perfringens food poisoning typically begins 6–24 h after consumption of the contaminated food and usually resolves within 24 h; for this reason, the disease is sometimes written off as a “stomach flu” or “24-hour flu.” Fatalities from perfringens food poisoning are rare, and no specific treatment is necessary other than replacing fluids lost from diarrhea or vomiting (if it occurs).

A diagnosis of perfringens food poisoning is made from isolation of *C. perfringens* from the feces or, more reliably, by an immunoassay that can detect *C. perfringens* enterotoxin in feces. Prevention of perfringens food poisoning requires that cooked foods not be contaminated with raw foods and that all foods be properly heated during cooking and home canning. The perfringens enterotoxin is heat-labile and thus any toxin that may have formed in a food product is destroyed by proper heating (75°C). Cooked foods not eaten immediately should be refrigerated as soon as possible to rapidly lower temperatures and inhibit the growth of any *C. perfringens* that may have been present.

Botulism

Botulism is a severe and potentially fatal food poisoning caused by the consumption of food containing the exotoxin produced by *C. botulinum* (Figure 33.9b). This bacterium normally inhabits soil or water, but its cells or endospores may contaminate raw and processed foods. If viable endospores of *C. botulinum* remain in the food, they may germinate and produce botulinum toxin; ingesting even a small amount of this highly poisonous substance can cause severe illness or death.

Botulinum toxin is a neurotoxin that affects autonomic nerves that control key body functions such as respiration and heartbeat; the typical result is a flaccid paralysis (◀ Section 25.6 and Figure 25.14). At least seven distinct botulinum toxins are known. Because the toxins are destroyed by heat (80°C for 10 minutes), thoroughly cooked food, even if contaminated with toxin, is harmless. Much foodborne botulism is from improperly processed home-canned foods, especially nonacidic foods such as corn, potatoes, and beans. Any viable *C. botulinum* endospores that remain in the sealed (and now anoxic) jar may germinate during storage and produce toxin. Many of these foods are used without cooking when making cold salads, and hence any botulinum toxin present is not destroyed. Prevention of foodborne botulism thus requires careful attention to canning and related food preservation practices.

Although infants can be poisoned by toxin-contaminated food, the majority of infant botulism cases occur from toxin produced following actual infection of the infant with *C. botulinum*. This occurs most commonly in newborns up to about 2 months of age because they lack a well-developed intestinal microbiota that can outcompete *C. botulinum*. Ingested *C. botulinum* endospores germinate in the infant's intestine, triggering growth and toxin production. Wound botulism can also occur from infection, presumably from endospores in contaminating material introduced via a parenteral route. Wound botulism is most commonly associated with illicit injectable drug use.

Figure 33.9 Food poisoning clostridia. (a) Gram stain of a growing culture of *Clostridium perfringens*, the bacterium that causes perfringens food poisoning. A cell measures about $1 \times 3 \mu\text{m}$. (b) Gram stain of a sporulating culture of *Clostridium botulinum*, the agent of botulism. A cell measures about $1 \times 5 \mu\text{m}$ and endospores (arrows) appear red.

In 2017, 182 cases of botulism were confirmed in the United States, most of which (141 cases; 77%) were infant botulism; cases of foodborne and wound botulism occurred less often and with equal frequency. Although rare, botulism is always serious because of the high mortality associated with untreated disease. However, because most cases are diagnosed and treated, less than 5% of all botulism cases result in death.

Botulism is diagnosed when either botulinum toxin or *C. botulinum* cells are detected in the patient (or in the contaminated food) coupled with clinical observations of localized paralysis (for example, impaired vision and speech) beginning 18–36 h after ingestion of the contaminated food. Treatment for botulism is by administration of botulinum antitoxin if the diagnosis is early, and mechanical ventilation if signs of respiratory paralysis have already appeared. If the dose of toxin is not too high, infant botulism is usually self-limiting, and most infants recover with only supportive therapy, such as assisted ventilation.

We move on now to consider food infections—afflictions distinct from food poisonings—with the “salmonella problem” taking stage front and center.

Check Your Understanding

- Compare and contrast toxin production and toxemia in botulism and perfringens food poisoning.
- Describe differences in the transmission of botulism in adults versus infants.

V • Food Infection

Food infections result from the ingestion of pathogens that colonize and multiply in the host and trigger symptoms that usually require medical intervention. *Salmonella* is one of the most notorious bacterial culprits in food infections, but viruses and parasites can also cause these maladies.

Recall that food *infection* is not the same thing as food *poisoning* (Section 33.7). Food infection results from ingestion of food containing sufficient numbers of viable pathogens to allow growth of the pathogen and disease in the host. Food infections are

common, and in the United States, the sum total of food infections outnumbers cases of food poisoning by nearly 10-fold. Sections 25.1 and 25.2 reviewed the infection process, summarizing the steps by which microorganisms—friend and foe alike—attach and become established in host tissues.

33.10 Salmonellosis

Salmonellosis is a gastrointestinal disease typically caused by ingesting food contaminated with *Salmonella* or by handling *Salmonella*-contaminated animals or animal products (Figure 33.10). Only *Campylobacter* (Section 33.12) produces more bacterial food infections than *Salmonella* (Table 33.5). Symptoms of salmonellosis begin after the pathogen—a gram-negative, facultatively aerobic rod related to *Escherichia coli* (Section 16.3 and see Figure 33.11)—colonizes the intestinal epithelium. *Salmonella* species normally inhabit the gastrointestinal tract of endothermic (warm-blooded) and many ectothermic (cold-blooded) animals (Figure 33.10) and are common in sewage. Thus, some cases of salmonellosis are waterborne rather than foodborne infections, and this is especially the case for typhoid fever (Section 33.5).

The accepted species epithet for pathogenic *Salmonella* is *enterica*, and there are seven subspecies of *S. enterica*. Most human-associated salmonellas fall into the *S. enterica* subspecies *enterica* group. Each subspecies is also divided into *serovars* (serological variants). Thus, there are *Salmonella enterica* serovar Typhi, or *Salmonella enterica* (*typhi*) for short, and *Salmonella enterica* serovar Typhimurium, and so on. *S. enterica* serovars Typhimurium and Enteritidis are most frequently associated with foodborne salmonellosis.

Pathogenesis and Epidemiology

The most common form of salmonellosis is *enterocolitis*. Ingestion of food containing viable cells of *Salmonella* results in colonization of both the small and large intestines. From here, cells of *Salmonella* invade phagocytic cells and grow intracellularly, spreading to adjacent cells as host cells die. After invasion, pathogenic *Salmonella* deploy several virulence factors, including endotoxins, enterotoxins, and cytotoxins that damage and kill host cells (Chapter 25). Symptoms of enterocolitis typically appear 12–72 h after ingestion and include a headache, chills, nausea, vomiting, and diarrhea, followed

by a fever that can last for several days. The disease normally resolves without intervention in 2–5 days. After recovery, however, patients may shed *Salmonella* in their feces for several weeks and some become healthy carriers. A few serovars of *S. enterica* may also cause septicemia (a blood infection) and enteric or typhoid fever, a potentially fatal disease characterized by systemic infection and high fever lasting several weeks (Section 33.5).

The incidence of salmonellosis in the United States has been steady over the last decade, with about 1.2 million estimated cases each year. There are several routes by which *Salmonella* may enter the food supply. The bacteria may reach food through fecal contamination from food handlers. Food production animals such as chickens, pigs, and cattle harbor *Salmonella* serovars that are pathogenic to humans, and these may be carried through to fresh foods such as eggs, meat, and dairy products (Figure 33.10d). *Salmonella* food infections are often traced to products such as custards, cream cakes, meringues, pies, and eggnog made with uncooked eggs. Other foods commonly implicated in salmonellosis outbreaks are meats and meat products, especially poultry, cured but uncooked sausages and other meats, milk, and milk products. The simple handling of *Salmonella*-contaminated animals, especially reptiles (Figure 33.10b), can also lead to salmonellosis.

Diagnosis, Treatment, and Prevention

Foodborne salmonellosis is diagnosed from a combination of clinical symptoms, a history of recent consumption of high-risk foods, and culturing of the organism from feces. Selective, differential media are used to isolate *Salmonella* and discriminate it from other gram-negative enteric bacteria (Figure 33.11). Tests for the presence of *Salmonella* are commonly carried out on foods of animal origin, such as raw meat, poultry, eggs, and powdered milk. Tests include several rapid tests (Chapter 29), but even rapid tests usually rely on enrichment procedures to increase cell numbers of *Salmonella* to testable levels.

Treatment of enterocolitis is usually unnecessary, and antibiotic treatment does not typically shorten the course of the disease or eliminate the carrier state. Foods containing *Salmonella* but heated to at least 70°C are generally safe if consumed immediately, held at 50°C or above, or quickly refrigerated. Any foods that become

contaminated by an infected food handler can support the growth of *Salmonella* if the food is held for a long enough period, especially if it is not kept very warm or refrigerated. A recently developed anti-*Salmonella* bacteriophage preparation, which is sprayed directly onto foods susceptible to *Salmonella* contamination, may help minimize the risk of salmonellosis, especially if refrigeration is unavailable.

Check Your Understanding

- Describe salmonellosis food infection. What foods and disease symptoms are typically associated with salmonellosis?
- How might *Salmonella* contamination of food production animals be contained?

33.11 Pathogenic *Escherichia coli*

Most strains of *Escherichia coli* are common microbiota in the human colon and are not pathogenic. However, a few strains are potential foodborne (and occasionally waterborne) pathogens (Figure 33.12) and produce potent enterotoxins (◀ Section 25.6). These pathogenic strains are grouped on the basis of the type of toxin they produce and their specific disease syndromes. We focus here on Shiga toxin-producing *E. coli* and briefly consider some other toxigenic *E. coli* strains.

Although not in the “top five” in terms of foodborne infection pathogens (Table 33.5), pathogenic *E. coli* strains cause disease symptoms so severe that they often require hospitalization. Indeed, infections with pathogenic *E. coli* may cause life-threatening diarrheal disease and urinary tract distress.

Shiga Toxin–Producing *Escherichia coli* (STEC)

Shiga toxin–producing *Escherichia coli* (STEC) strains produce *verotoxin*, an enterotoxin similar to the Shiga toxin produced by *Shigella dysenteriae*, a close relative of *E. coli*. This toxin inhibits protein synthesis and induces a bloody diarrhea (dysentery) and kidney failure. STEC strains of *E. coli* are also called *enterohemorrhagic E. coli* (EHEC). The most widely distributed STEC is *E. coli* O157:H7 (Figure 33.12b). Following ingestion of food or water containing STEC (as few as 10 cells can trigger the disease), the bacteria infect the small intestine where they grow and produce verotoxin, which both causes a bloody diarrhea and initiates signs of kidney failure.

Nearly half of STEC infections are caused by the consumption of contaminated uncooked or undercooked meat, particularly mass-processed ground beef. *E. coli* O157:H7 is normally present in the intestines of healthy cattle and enters the human food chain if meat is contaminated with the animal’s intestinal contents during slaughter and processing. STEC strains have also been implicated in food infection outbreaks caused by dairy products (especially raw milk products), fresh fruit, and raw vegetables. Contamination of the fresh foods by fecal material, typically from cattle carrying STEC strains, has been implicated in several of these cases (Section 33.7).

Other Pathogenic *Escherichia coli*

Children in developing countries often contract diarrheal disease caused by *E. coli*, and *E. coli* can also be the cause of “traveler’s diarrhea,” a common infection causing watery diarrhea (as opposed to the bloody diarrhea of STEC strains) in travelers to developing

Figure 33.11 Isolation of *Salmonella*. (a) Colonies of *S. enterica* (typhimurium) on Hektoen agar, which contains inhibitors of gram-positive bacteria and both lactose and peptone as carbon sources. Thiosulfate in the medium is reduced to H_2S by *Salmonella* and complexes with iron to form black FeS. *Salmonella* thus forms white colonies with black FeS centers, a pattern unique among enteric bacteria. The blue color results from the medium turning alkaline because *Salmonella* species do not ferment lactose and instead consume the amino acids in peptone. (b) Gram stain of cells of *Salmonella*; an average cell is about $1 \times 3 \mu m$.

Figure 33.12 Pathogenic *Escherichia coli*. (a) Gram-stained cells showing the typical gram-negative, rod-shaped morphology of *E. coli*. (b) Colorized scanning electron micrograph of cells of *E. coli* O157:H7. Cells measure about $1 \times 3 \mu\text{m}$. (c) *E. coli* can be easily isolated on various selective and differential culture media such as Hektoen agar, where colonies of *E. coli* turn yellow because this bacterium ferments lactose and acidifies the medium (compare these with colonies of *Salmonella* on Hektoen agar in Figure 33.11a). (d) Enteropathogenic strains of *E. coli* can be detected, as in this fecal smear, using a specific fluorescent antibody (◀ Section 29.6).

countries. The primary causal agents here are *enterotoxigenic E. coli* (ETEC, Figure 33.12d). These strains infect the small intestine and produce one of two heat-labile, diarrhea-producing enterotoxins.

In studies of United States citizens traveling in Mexico, the infection rate with ETEC is often greater than 50%. The major vehicles are perishable foods, such as fresh vegetables (for example, lettuce in salads), and public water supplies. The local population is typically resistant to the ETEC strains because of long-term contact with the organism. Other pathogenic *E. coli* strains include *enteropathogenic E. coli* (EPEC) strains that cause diarrheal diseases in infants and small children but do not cause invasive disease or produce toxins, and *enteroinvasive E. coli* (EIEC) strains, which invade the colon and cause watery and sometimes bloody diarrhea.

Diagnosis, Treatment, and Prevention

The general pattern established for the diagnosis, treatment, and prevention of STEC infection reflects current procedures used for all pathogenic *E. coli* strains. Laboratory diagnosis can be accomplished by culturing the pathogen from a fecal sample (Figure 33.12c) and identifying the O (lipopolysaccharide) and H (flagellar) antigens and toxins by immunological methods (Figure 33.12d). Identification and typing can also be done using various molecular analyses, and rapid tests to detect Shiga toxin are also now available (◀ Section 29.7).

Treatment of STEC infections includes supportive care for dehydration and monitoring of renal function, blood hemoglobin, and platelets. Bactericidal antibiotics may actually be harmful because they may trigger the release of large amounts of verotoxin from

dying *E. coli* cells that would otherwise be voided intact in feces. For other pathogenic *E. coli* infections, treatment includes supportive therapy and, for severe cases and invasive disease, antimicrobial drugs to shorten and eliminate infection.

The most effective way to prevent infection with pathogenic *E. coli* of any type is to wash raw foods vigorously and make sure that meat, especially ground beef, is cooked thoroughly, which means that it should appear gray or brown with clear juices and have attained a temperature of greater than 70°C . In general, proper food handling, water purification, and appropriate hygiene also prevent the spread of pathogenic *E. coli*. Travelers can avoid diarrhea from pathogenic *E. coli* by drinking only properly sealed bottled water and avoiding any uncooked foods.

Check Your Understanding

- How do STEC strains of *Escherichia coli* differ from other pathogenic *E. coli*?
- Why are meats prime vehicles for pathogenic *E. coli*? How can contaminated meat be rendered safe to eat?

33.12 *Campylobacter*

Causing an estimated 1.3 million cases every year, *Campylobacter* infection has usurped salmonellosis (Section 33.10) as the most prevalent bacterial foodborne disease in the United States in recent years (Table 33.5). Cells of *Campylobacter* are gram-negative and motile spiral-shaped *Epsilonproteobacteria* (◀ Section 16.5) that grow best at reduced oxygen tension (microaerophilic). Several species of *Campylobacter* are recognized, but *C. jejuni* and *C. fetus* (Figure 33.13) are the most commonly linked to human foodborne illnesses.

Epidemiology and Pathology

Campylobacter is transmitted to humans via contaminated food, most commonly in undercooked poultry or pork, raw shellfish, or occasionally in feces-contaminated water from surface sources. *C. jejuni* is a normal resident of the intestinal tract of poultry, and according to the United States Department of Agriculture, up to 90% of turkey and chicken carcasses are contaminated with *Campylobacter*. Pork can also carry *Campylobacter*, while beef is rarely a vehicle. *Campylobacter* species also infect domestic animals such as dogs, causing a milder form of diarrhea in the animal than that observed in humans. *Campylobacter* infections in infants in particular are often traced to infected domestic animals, especially puppies and kittens, from which the bacteria are transmitted to children through the fecal–oral route.

After cells of *Campylobacter* are ingested, the organism multiplies in the small intestine, invades the epithelium, and causes inflammation. Because *C. jejuni* is sensitive to gastric acid, cell numbers as high as 10^4 may be required to initiate infection. However, this number may be reduced to fewer than 500 cells if the pathogen is ingested in food or if the person is taking medication to reduce stomach acid production. *Campylobacter* infection causes a high fever (usually greater than 40°C), headache, malaise, nausea, abdominal cramps, and diarrhea with watery, frequently bloody emissions; symptoms subside in about a week.

Figure 33.13 *Campylobacter*. (a) Colonies of *C. jejuni* grown on *Campylobacter* agar, a selective medium. The medium contains several antibiotics to which *Campylobacter* species are naturally resistant. (b) Gram stain and (c) scanning electron micrograph of cells of a *Campylobacter* species. Single cells average $0.4 \times 2 \mu\text{m}$ in size.

Diagnosis, Treatment, and Prevention

Diagnosis of *Campylobacter* food infection requires isolation of the organism from feces and identification by growth-dependent tests, immunological assays, or genomic analyses. Culture media containing multiple antibiotics to which campylobacters are naturally resistant have been developed for selective isolation of this organism (Figure 33.13a). Various immunological methods are also available for diagnosing a campylobacter infection.

Antibiotic treatment with the drug azithromycin is widely practiced if a confirmed diagnosis is made from culture or culture-independent evidence. In addition, severe cases of dehydration from a *Campylobacter* infection may require intravenous perfusion and hospitalization. Rigorous personal hygiene, especially by those in food preparation facilities, proper washing of uncooked poultry (and any kitchenware coming in contact with uncooked poultry, such as cutting boards), and thorough cooking of meat are the major means of preventing *Campylobacter* infections.

Check Your Understanding

- Describe the pathology of *Campylobacter* food infection. What are the major vehicles for this pathogen?
- How might *Campylobacter* contamination of food production animals be controlled?

33.13 Listeriosis

Listeria monocytogenes causes **listeriosis**, a gastrointestinal food infection that may lead to bacteremia (bacteria in the blood) and meningitis. *L. monocytogenes* is a gram-positive, nonsporulating

coccobacillus (phylum *Firmicutes*) that is acid-, salt-, and cold-tolerant and facultatively aerobic (Figure 33.14; ◀ Section 16.7). Although *Listeria* is a minor foodborne pathogen in terms of the number of cases observed per year, infections can be severe and cause up to 25% of all deaths from foodborne illness in the United States. Listeriosis is primarily seen in the elderly, pregnant women, newborns, and adults with weakened immune systems. Every year, *L. monocytogenes* is estimated to cause 1600 cases of invasive listeriosis (infection beyond the gastrointestinal tract), leading to about 260 deaths (16% mortality).

Epidemiology

L. monocytogenes is present in soil and water and although it is not common in foods, virtually no food source is safe from possible *L. monocytogenes* contamination. Food can become contaminated at any stage during production or processing. Ready-to-eat meats, fresh soft cheeses, unpasteurized dairy products, and inadequately pasteurized milk are the major food vehicles for *Listeria*, even when these foods are properly stored at refrigerator temperature (4°C). Food preservation by refrigeration, which ordinarily prevents the growth of other foodborne pathogens, is ineffective in the case of *Listeria* because the organism is psychrotolerant. Cells of *L. monocytogenes* produce a series of branched-chained fatty acids that keep the cytoplasmic membrane functional at cold temperatures (◀ Section 4.12).

Pathology

Immunity to *L. monocytogenes* is normally conferred by cell-mediated Th1 inflammatory cells (◀ Section 27.8). However, if cells of *Listeria* evade these immune cells, as they can in hosts with compromised immune systems, the organism is taken up by intestinal phagocytic cells. Although one might think that this is good from the standpoint of host defense, it is actually not, because phagocytic uptake initiates the *Listeria* infection cycle.

Listeria cells are taken up by host phagocytic cells into a vacuole called the *phagosome*. This triggers production of a major *Listeria* virulence factor, the exotoxin *listeriolysin O*, and this protein lyses the phagosome and releases *L. monocytogenes* into the cytoplasm (Figure 33.15a; see also MicrobiologyNow in Chapter 1). Here the bacterium multiplies and produces a second major virulence factor,

Figure 33.14 *Listeria monocytogenes*. (a) Gram stain and (b) transmission electron micrograph of cells of *L. monocytogenes*, the cause of listeriosis. Cells measure about $0.5 \times 1 \mu\text{m}$. The *Listeria* cell in b is within host tissues (see Figure 33.15).

Figure 33.15 Transmission of *Listeria* during listeriosis. (a) Cells of *Listeria* are taken up in phagosomes of phagocytic cells. These are eventually lysed by the virulence factor listeriolysin O to release *Listeria* cells into the cytoplasm. The bacterial cells then become covered with host cell actin that assists in their movement to the cell periphery. Filopodia facilitate transfer of *Listeria* cells to neighboring host cells, where the cycle repeats. (b) Fluorescently stained cells of *Listeria monocytogenes* (red) showing actin-assisted motility inside a eukaryotic cell (actin stains green, and the host cell nucleus is blue). The dashed white line labels the boundary between the two eukaryotic cells.

Mastering
Microbiology
Art Activity:
Figure 33.15
Transmission of
Listeria during
listeriosis

ActA, a protein that induces host cell actin polymerization; the actin coats the bacterial cell and assists in moving the pathogen to the host cell cytoplasmic membrane (Figure 33.15b). Once there, the bacterium–actin complex pushes out, forming protrusions called *filopods*, which are then taken up by surrounding phagocytic cells (Figure 33.15a). Filopod formation allows cells of *L. monocytogenes* to move about host tissues without exposure to the major weapons of the immune system: antibodies, complement, and neutrophils (Chapters 26 and 27).

Cells of *Listeria* in the intestine cross the intestinal barrier and are carried by the lymph and blood to other organs, in particular the liver, and multiply there as they do in intestinal phagocytes. From here cells of *L. monocytogenes* can infect the central nervous system, where they grow in neurons and lead to inflammation of the meninges (the tissues covering the brain and spinal cord), causing meningitis. In addition to listeriolysin O, which also allows *Listeria* to establish chronic infections in many host tissues, other major virulence factors include phospholipases that can destroy host cell membranes, antioxidants that counter phagocytic cell oxidants, and an array of “stress proteins” common in many bacteria (Section 7.9).

Diagnosis, Treatment, and Prevention

Listeriosis is diagnosed by culturing *L. monocytogenes* (Figure 33.14) from the blood or cerebrospinal fluid. *L. monocytogenes* can be identified in foods by direct culture or by several molecular methods. The latter methods are also used to subtype clinical isolates in order to track the source(s) of infection. Intravenous antibiotic treatment

with penicillin, ampicillin, or trimethoprim plus sulfamethoxazole (Bactrim®) is used to treat invasive listeriosis.

Prevention measures include recalling contaminated food and taking steps to limit *L. monocytogenes* contamination at the food-processing site. Because *L. monocytogenes* is susceptible to heat and radiation, raw food and food-handling equipment can be readily decontaminated. However, unless the finished food product is pasteurized (Section 4.17) or cooked, the risk of contamination cannot be eliminated because of the widespread distribution of the pathogen.

Check Your Understanding

- What is the likely outcome of *Listeria monocytogenes* exposure in normal healthy individuals?
- Which populations are most susceptible to serious disease from *L. monocytogenes* infection?

33.14 Other Foodborne Infectious Diseases

Over 200 microorganisms, viruses, and other infectious agents can cause foodborne diseases, and we have thus far summarized the major ones. Here we consider a few other bacterial pathogens that are rather uncommon compared with the “top five” (Table 33.5), and we take a second look at norovirus (previously considered as a waterborne pathogen, Section 33.5) in its more frequent context as a foodborne pathogen and overall number one cause of gastrointestinal illness in the United States.

Figure 33.16 Less common foodborne bacterial pathogens: *Yersinia enterocolitica* and *Bacillus cereus*. (a) Gram-stained cells of *Y. enterocolitica*. (b) Colonies of *Y. enterocolitica* on Hektoen agar, a selective and differential medium. *Y. enterocolitica* forms white colonies because this bacterium does not ferment lactose and does not produce sulfide (compare with colonies of *Salmonella* on Hektoen agar in Figure 33.11a and colonies of *Escherichia coli* on Hektoen agar in Figure 33.12c). (c) Gram-stained cells of a sporulating culture of *B. cereus*. (d) Large crystalline-like colonies of *B. cereus* formed on blood agar. Foodborne illness due to *Y. enterocolitica* or *B. cereus* is much less common than illness due to *Salmonella*, *Campylobacter*, or *Clostridium perfringens*.

Bacteria

Besides the major bacterial foodborne pathogens we have already considered, several other bacteria cause human gastrointestinal illnesses. *Yersinia enterocolitica* is an enteric bacterium commonly found in the intestines of domestic animals and causes foodborne infections from contaminated meat and dairy products. The most serious consequence of *Y. enterocolitica* infection is *enteric fever*, a severe, life-threatening infection. *Y. enterocolitica* can be isolated on the same selective, differential medium used to isolate *Salmonella* (Figure 33.16a, b) but is easily distinguished from this organism on plates (compare Figures 33.11a and 33.16b).

Bacillus cereus is responsible for a relatively small number of food poisoning cases. This endospore-producing bacterium (◀ Sections 2.8 and 16.8) produces two enterotoxins that cause different symptoms. In the *emetic form*, symptoms are primarily nausea and vomiting. In the *diarrheal form*, diarrhea and gastrointestinal distress are observed. *B. cereus* grows in foods such as rice, pasta, meats, or sauces that are cooked and left at room temperature to cool slowly. When endospores of this bacterium germinate, toxin is produced. Reheating may kill the *B. cereus* cells, but the toxin is heat-stable and may remain active. *B. cereus* is readily culturable and can be tentatively identified by a combination of microscopy and its typically large, grainy, and spreading colonies (Figure 33.16c, d).

The enteric bacterium *Shigella* causes the food infection *shigellosis*, and species of *Vibrio* can also cause food poisoning, primarily from consumption of contaminated shellfish. Most *Shigella* infections are the result of fecal to oral contamination, but food and water are occasional vehicles. We discussed the Shiga-like toxin produced by some pathogenic strains of *Escherichia coli* in Section 33.11.

Viruses

About 70% of annual foodborne infections in the United States are caused by norovirus (Figure 33.17a; Section 33.5). The virus is also known as *Norwalk virus* and is a single-stranded plus-sense RNA virus related to poliovirus (◀ Section 11.8). In general, noroviral foodborne illnesses are characterized by diarrhea, often accompanied by nausea and recurrent vomiting. Recovery from norovirus infections is typically spontaneous and rapid, usually within 24–48 h (thus the disease is often nicknamed “the 24-hour bug”).

Rotavirus, astrovirus, and hepatitis A make up the bulk of the remaining foodborne viral infections. These viruses inhabit the gut

and are often transmitted in food or water contaminated with feces. Hepatitis A virus (HAV, Figure 33.17b) is an RNA virus that, like norovirus, is related to poliovirus, but HAV replicates in liver cells. We considered hepatitis viruses transmitted primarily by blood in Section 31.11, but HAV is mainly a foodborne virus. HAV usually triggers mild, and in many cases subclinical, symptoms, but rare cases of severe liver disease from HAV can occur. The most significant food vehicles for HAV are shellfish, usually oysters or clams harvested from water polluted by human feces and then eaten raw. In recent years, HAV has also been seen in fresh produce served without cooking.

Despite a slight uptick in incidence in recent years, the general trend for both foodborne and bloodborne hepatitis has moved steadily downward and is now at low levels, partly due to the availability of effective vaccines against both hepatitis A and hepatitis B (HBV) viruses (◀ Figure 31.32), but also because of heightened awareness of the potential danger of eating raw shellfish. Nevertheless, widespread and likely mild HAV infections continue to occur because surveys have shown that over 30% of individuals in the United States have circulating antibodies to HAV, indicating past subclinical infections. In 2016, 2007 cases of hepatitis A were reported in the United States.

Protists and Other Agents

Important foodborne protist diseases are listed in Table 33.5. The major pathogens here include *Giardia intestinalis*, *Cryptosporidium*

Figure 33.17 Viruses transmitted in contaminated foods. (a) Transmission electron micrograph of norovirus; an individual virion is about 30 nm in diameter. (b) Transmission electron micrograph of hepatitis A virus; a virion is 27 nm in diameter.

parvum, *Cyclospora cayetanensis*, and *Toxoplasma gondii*. *G. intestinalis* and *C. parvum* are spread in foods when contaminated water is used to wash, irrigate, or spray crops. Fresh foods such as fruits are often implicated as vehicles for these protists. *Toxoplasma gondii* is a protist spread primarily through cat feces, but it can also be found in raw or undercooked meat, especially pork. The incidence of foodborne transmission of *C. cayetanensis* has remained low (fewer than 20 cases per year) in recent years, and fresh cilantro and related produce have been the major vehicles of this pathogen in the majority of outbreaks. We discuss the diseases giardiasis, cryptosporidiosis, cyclosporiasis, and toxoplasmosis in Section 34.4.

At least one type of foodborne disease agent is neither cellular nor viral; these are the prions. *Prions* are proteins that adopt novel conformations, inhibiting normal protein function and causing degeneration of host neural tissues (◀ Section 11.13). Human prion diseases are characterized by neurological symptoms including

depression, loss of motor coordination, and eventual dementia. A foodborne human prion disease called *variant Creutzfeldt–Jakob disease* (vCJD) has been linked to consumption of meat products from cattle suffering from *bovine spongiform encephalopathy* (BSE), a disease caused by a prion. Although several thousand cases of vCJD were diagnosed in Great Britain in the mid-1990s, bans on cattle feeds containing rendered cattle and sheep parts and bone meal have greatly diminished the incidence of BSE in Europe and have kept the incidence of this disease extremely low in the United States.

Check Your Understanding

- In what two forms can *Bacillus cereus* food poisoning manifest itself?
- Compared with all other foodborne or waterborne pathogens, what is unique about prions?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Water as a Disease Vehicle

- 33.1** Contaminated drinking and recreational waters are sources of waterborne pathogens. In the United States, the number of disease outbreaks due to these sources is relatively small in relation to the large exposure the population has to water. Worldwide, lack of adequate water treatment facilities and access to clean water contribute significantly to the spread of infectious diseases.

Q What determines whether or not a pathogen present in a water source will lead to a person being infected with a waterborne disease?

- 33.2** Drinking water quality is determined by counting coliform and fecal coliform bacteria using standardized techniques. Filtration and chlorination of water significantly decreases microbial numbers. Water purification methods in developed countries have been a major factor in improving public health, although in developing countries, waterborne illness is still a significant source of infectious disease.

Q Describe how ATP can be used as a tool for estimating total bacterial numbers in a given water sample.

II • Waterborne Diseases

- 33.3** The bacterium *Vibrio cholerae* causes cholera, an acute diarrheal disease associated with severe dehydration. Cholera occurs in epidemics, primarily in developing countries where sewage treatment and sanitation is lacking. Oral rehydration and electrolyte replacement can effectively treat cholera and greatly reduce disease mortality.

Q Describe the mode of action of *V. cholerae* on the small intestine in the body.

- 33.4** *Legionella pneumophila* is a respiratory pathogen that causes Pontiac fever and legionellosis, a more serious infection that may result in pneumonia. *L. pneumophila* grows to high numbers in warm waters and is spread via cooling tower aerosols and in domestic water distribution systems where the bacterium develops in biofilms.

Q How is *L. pneumophila* usually detected, and what are the various means of treating legionellosis in an infected patient?

- 33.5** Typhoid fever, caused by a *Salmonella* species, and norovirus illness are important waterborne diseases. Typhoid is common in developing countries, while norovirus illness is seen worldwide. Both of these diseases can be controlled by good sanitation practices and effective water treatment.

Q How is *S. enterica*, the causative agent of typhoid fever, transmitted? What are the stages of typhoid fever?

III • Food as a Disease Vehicle

- 33.6** The potential for microbial food spoilage depends on the nutrients and moisture levels of the food. Growth of microorganisms in perishable foods can be controlled by refrigeration, freezing, canning, pickling, dehydration, chemicals, and irradiation. Microbial fermentations can be used to naturally preserve many foods, including dairy products, meats, fruits and vegetables, and alcoholic beverages.

Q Identify and define the three major categories of food perishability. Why is milk more perishable than sugar even though both are rich in organic matter? Identify the major methods used to preserve food and the major categories of fermented foods.

33.7 Food poisoning results from the activities of microbial toxins, whereas food infections are due to the growth of the pathogen within the body. Identification of shared characteristics of foodborne pathogens from seemingly isolated foodborne outbreaks can pinpoint the origin of foodborne contamination and track the spread of the disease. The top five most prevalent foodborne pathogens in the United States are (1) norovirus, (2) *Campylobacter jejuni*, (3) *Salmonella* spp., (4) *Clostridium perfringens*, and (5) *Staphylococcus aureus*.

Q Distinguish between food infection and food poisoning, and give two examples of each.

IV • Food Poisoning

33.8 Staphylococcal food poisoning results from the ingestion of a preformed staphylococcal enterotoxin, a superantigen produced by cells of *Staphylococcus aureus* as they grow in food. Proper food preparation, handling, and storage can prevent staphylococcal food poisoning.

Q What causes the symptoms of staphylococcal food poisoning? Why are cases of staph food poisoning often linked to a food preparer?

33.9 *Clostridium* food poisoning results from ingestion of toxins produced by microbial growth in foods or from microbial growth followed by toxin production in the body. Perfringens food poisoning is quite common and is usually a self-limiting gastrointestinal disease. Botulism is a rare but serious disease having significant mortality.

Q Identify the two major types of clostridial food poisoning. Which is most prevalent? Which is most dangerous and why?

V • Food Infection

33.10 About 1.2 million cases of salmonellosis occur every year in the United States. Infection results from ingestion of cells of *Salmonella* introduced into food primarily from animal-derived food products or food handlers.

Q What are the possible sources of *Salmonella* spp. that cause food infections?

33.11 Toxigenic *Escherichia coli* strains cause many food infections, and of these, STEC strains are the most severe. Contamination of foods from animal feces spreads these pathogenic strains of *E. coli*, but good hygiene practices and specific antibacterial measures, such as irradiation or thorough cooking of ground beef, a major vehicle, can control disease outbreaks.

Q How does *Escherichia coli* O157:H7 end up in ground beef? To what class of pathogenic *E. coli* does this strain belong? How does this class differ from other classes?

33.12 With an incidence of 1.3 million cases per year, *Campylobacter* infection is the most prevalent foodborne bacterial disease in the United States. Poultry is a major vehicle for *Campylobacter* illness, whereas beef and pork are not. Proper poultry preparation and cooking can prevent *Campylobacter* illness.

Q Name a food product that could transmit both *Salmonella* and *Campylobacter* simultaneously. How could this food product be rendered safe to eat?

33.13 *Listeria monocytogenes* is a ubiquitous bacterium, and in healthy individuals, it seldom causes infection. However, in immunocompromised individuals, *Listeria* can cause serious disease as it grows as an intracellular pathogen and invades the central nervous system. Listeriosis is uncommon but shows high mortality.

Q Identify the food sources of *Listeria monocytogenes* infections. How does *Listeria* evade the immune system?

33.14 Viruses, especially norovirus, cause the highest incidence of foodborne illness, whereas the bacteria *Bacillus cereus*, *Shigella* spp., and *Yersinia enterocolitica* are only occasionally linked to foodborne disease outbreaks. Hepatitis A virus is also a serious foodborne pathogen. Some protists and prions also cause foodborne illness but are far less common foodborne pathogens than are bacteria and viruses.

Q What agent is the number one cause of gastrointestinal illness? What is the causative agent of vCJD? How does the structure of this agent differ from that of norovirus?

APPLICATION QUESTIONS

- As a visitor to a country in which cholera is an endemic disease, what specific steps would you take to reduce your risk of cholera exposure? Will these precautions also prevent you from contracting other waterborne diseases? If so, which ones? Identify waterborne diseases for which your precautions may not prevent infection.
- Argue a case for why perfringens foodborne illness can be considered both a food poisoning and a food infection.
- Improperly prepared or handled potato salads are often the source of both staphylococcal food poisoning and salmonellosis. List some reasons why this might be the case. How do these differ from foodborne disease caused by *Clostridium botulinum*?
- Both enterotoxigenic *Escherichia coli* and *Clostridium botulinum* cause foodborne illnesses. However, cells of one of these pathogens are rarely detected in the feces of a patient suffering from the disease, whereas cells of the other can be readily detected. Explain.

CHAPTER GLOSSARY

Botulism food poisoning due to ingestion of food containing botulinum toxin produced by *Clostridium botulinum*

Coliforms gram-negative, nonsporulating, facultatively aerobic rods that ferment lactose with gas formation within 48 hours at 35°C

Food infection a microbial infection resulting from the ingestion of pathogen-contaminated food followed by growth of the pathogen in the host

Food poisoning (food intoxication) a disease caused by the ingestion of food that contains preformed microbial toxins

Food spoilage a change in the appearance, smell, or taste of a food that makes it unacceptable to the consumer

Listeriosis a gastrointestinal food infection caused by *Listeria monocytogenes* that may lead to bacteremia and meningitis

Nonperishable foods foods of low water activity that have an extended shelf life and are resistant to spoilage by microorganisms

Pasteurization the use of controlled heat to reduce the microbial load, including both pathogens and spoilage organisms, in heat-sensitive liquids

Perishable foods fresh foods generally of high water activity that have a very short shelf life because of spoilage by microbial growth

Potable in water purification, drinkable; safe for human consumption

Salmonellosis enterocolitis or other gastrointestinal disease caused by any of several subspecies of the bacterium *Salmonella*

Semiperishable foods foods of intermediate water activity that have a limited shelf life because of their potential for spoilage by growth of microorganisms

Eukaryotic Pathogens: Fungi, Protozoa, and Helminths

34

MICROBIOLOGYNOW

A Silver Bullet to Kill Brain-Eating Amoebae?

One of the most difficult-to-treat infectious diseases is primary amebic meningoencephalitis (PAM), caused by the “brain-eating” parasitic amoeba *Naegleria fowleri*. Although fewer than five cases are reported annually in the United States, *N. fowleri* infections are nearly always fatal and are linked to swimming in warm, stagnant, natural waters. If such waters are accidentally inhaled, the highly invasive amoebae (yellow cells in the photomicrograph) can attach to nasal epithelial cells and burrow to the central nervous system (CNS); there they begin to ingest brain cells (red in photo) and multiply quickly. The disease progresses rapidly, and death usually occurs within a few days.

PAM is difficult to treat for two key reasons. First, because it is so rare, diagnosis is often delayed, with the unfortunate result being cerebral hemorrhaging and rapid loss of brain cells to the voracious amoebae. Second, the pathogen in this case is a eukaryote. Thus, significant similarities between cells of the amoeba and those of the host often produce unwanted side effects when antiparasitic drugs are administered, especially at the high concentrations required to treat CNS infections.

I Fungal Infections 1060

II Visceral Parasitic Infections 1064

III Blood and Tissue Parasitic Infections 1067

A current trend in modern clinical medicine is to accelerate drug development for serious diseases by repurposing pharmaceuticals already approved by the U.S. Food and Drug Administration. In this connection, one research group recently tested three anti-seizure drugs (diazepam, marketed as Valium®; phenobarbital, marketed as Luminal®; and phenytoin, marketed as Dilantin®), which readily cross the blood–brain barrier, for cytotoxic effects against *N. fowleri*. Although the drugs alone could kill cells of *N. fowleri*, cytotoxicity was greatly amplified when the drugs were attached to silver nanoparticles, which are known to have antimicrobial activity.

As demonstrated by this study, the modification and repurposing of existing drugs may prove to be a key strategy for the rapid development and implementation of new disease therapies moving forward.

Source: Anwar, A., et al. 2019. Clinically approved drugs against CNS diseases as potential therapeutic agents to target brain-eating amoebae. *ACS Chem. Neurosci.* 10: 658. doi: 10.1021/acschemneuro.8b00484.

In this chapter we focus on *eukaryotic* pathogenic microorganisms. These include fungi—both molds and yeasts—and various parasitic protists. Some small helminths (worms) also cause infectious diseases, and we consider the most significant of these in the final section.

A common problem in treating human diseases caused by eukaryotic pathogens is the fact that humans are also eukaryotes. This thwarts many therapeutic strategies and often results in these diseases being highly refractory and chronic infections. This is especially true of systemic fungal pathogens, a group we consider first in our coverage of eukaryotic pathogenic microbes.

I • Fungal Infections

Pathogenic fungi cause a variety of diseases ranging from superficial and subcutaneous skin infections that are relatively easy to treat to serious systemic mycoses. The latter are deep-seated, potentially life-threatening infections that are much more difficult to treat.

Fungi cause a variety of human diseases. Some are mild and self-limiting, whereas others can be firmly entrenched systemic diseases. We begin by considering some of the major fungal pathogens followed by a description of some major fungal diseases, the mycoses.

34.1 Pathogenic Fungi and Classes of Infection

The fungi include the *yeasts*, which normally grow as single cells, and *molds*, which form branching filaments called *hyphae* with or without septa (cross-walls); hyphae eventually intertwine to form visible masses called *mycelia*. The diversity of the molds and yeasts was discussed in Chapter 18.

Common Fungal Pathogens

Fortunately, most fungi are harmless to humans. Most fungi grow in nature as saprophytes on dead organic material, and in so doing, fungi are important catalysts in the carbon cycle, especially in oxic environments in soil. Fungi are also important in medicine both as agents of disease and in chemotherapy (as producers of antibiotics). Only about 50 species of fungi cause human diseases, and in healthy individuals, the incidence of serious fungal infections is low, although certain superficial fungal infections (for example, athlete's foot) are common. In those with compromised immune systems, however, fungal infections can be systemic, reaching even the deepest of internal tissues. Such infections can cause serious health problems and be life-threatening.

Common fungal pathogens include both yeasts and molds (Figure 34.1). However, many pathogenic fungi are *dimorphic*, meaning that they can exist as *either* a yeast *or* in filamentous form, a feature

Figure 34.1 Pathogenic fungi. These organisms range from about 4 to 20 μm in diameter. (a) *Cryptococcus neoformans* yeast cells stained to reveal the capsule. (b) *Trichophyton maritii* mycelia and hyphae. (c) *Candida albicans* yeast form stained with a fluorescent antibody. (d) *Sporothrix schenckii* mycelia and conidia. (e) *Histoplasma capsulatum* mycelia and large conidia. (f) *Coccidioides immitis* conidia. See fungal disease symptoms in Figure 34.5.

typically dictated by environmental factors, such as temperature and moisture levels. In *Histoplasma*, for example, cells in laboratory culture form hyphae and mycelia and thus exist in the mold form (Figure 34.1e). By contrast, when *Histoplasma* causes histoplasmosis, cells grow in the host in the yeast form (see Figure 34.5a). In the mold form, spores are produced, either asexual spores—*conidia*—or sexual spores (◀ Section 18.10). When filamentous fungi are cultured from an infection, the morphology of these spore-bearing structures is observed and is often a major clue in reaching a diagnosis. In addition to microscopy, a variety of clinically useful molecular and immunological tools (including fluorescent antibodies, Figure 34.1c) are also available to diagnose fungal infections. Table 34.1 lists some major fungal pathogens and the types of infections they cause.

Fungal Disease Classes and Treatment

Fungi cause disease through three major mechanisms: inappropriate immune responses, toxin production, and mycosis. Some fungi trigger immune responses that result in allergic (hypersensitivity) reactions following exposure to specific fungal antigens. Reexposure to the same fungi, whether growing on the host or in the environment, may cause allergic symptoms. For example, *Aspergillus* spp. (Figure 34.2a), common saprophytes often found in nature as a leaf mold, produce potent allergens, triggering asthma attacks or other hypersensitivity reactions in susceptible individuals.

TABLE 34.1 Major pathogenic fungal diseases ^a		
Diseases by class	Causal organism	Site
Superficial mycoses		
Athlete's foot	<i>Epidermophyton</i> , <i>Trichophyton</i>	Between toes, skin
Jock itch	<i>Trichophyton</i> , <i>Epidermophyton</i>	Genital region
Ringworm	<i>Microsporum</i> , <i>Trichophyton</i>	Scalp, face
Subcutaneous mycoses		
Sporotrichosis	<i>Sporothrix schenckii</i>	Arms, hands
Chromoblastomycosis	<i>Phialophora verrucosa</i> , other fungi	Legs, feet, hands
Systemic mycoses		
Aspergillosis	<i>Aspergillus</i> spp. ^b	Lungs
Blastomycosis	<i>Blastomyces dermatitidis</i>	Lungs, skin
Candidiasis	<i>Candida albicans</i> ^c	Oral cavity, intestinal tract, vagina
Coccidioidomycosis	<i>Coccidioides immitis</i> ^c	Lungs
Paracoccidioidomycosis	<i>Paracoccidioides brasiliensis</i>	Skin
Cryptococcosis	<i>Cryptococcus neoformans</i> ^c	Lungs, meninges
Histoplasmosis	<i>Histoplasma capsulatum</i> ^c	Lungs
Pneumocystis pneumonia	<i>Pneumocystis jirovecii</i> ^c	Lungs

^aSymptoms of many of these diseases are shown in Figures 34.3–34.5.
^b*Aspergillus* can also cause allergies, toxemia, and limited infections.
^cAn opportunistic pathogen frequently infecting individuals with HIV/AIDS.

Figure 34.2 *Aspergillus* and aflatoxin. (a) Mycelia and conidia of an *Aspergillus* species. (b) Structure of aflatoxin B1. This toxin is one of a group of related compounds produced by *Aspergillus flavus*.

Fungal disease may occur from the production of *mycotoxins*, a large and diverse group of fungal exotoxins (◀ Section 25.6). The best-known examples of mycotoxins are the *aflatoxins* (Figure 34.2b) produced by *Aspergillus flavus*, a species that commonly grows on improperly stored dry foods, such as grain. Aflatoxins are highly toxic and are also carcinogenic, inducing tumors in some animals, especially in birds that feed on contaminated grain. Although aflatoxins are known to cause human liver damage including cirrhosis and even liver cancer, adults are not seriously affected by low-level aflatoxin exposure. However, chronic exposure in children can cause serious liver disease and stunt normal growth and development.

The final fungal disease-producing mechanism is through actual host infection. The growth of a fungus on or in the body is called a **mycosis** (plural, mycoses). Mycoses are fungal infections that range in severity from superficial to life-threatening. Mycoses fall into three classes (Table 34.1). **Superficial mycoses** are those in which the fungus infects only the surface layers of skin, hair, or nails (see Figure 34.3). **Subcutaneous mycoses** are infections of deeper layers of skin (see Figure 34.4) and are typically caused by different fungi than superficial infections (Table 34.1). The **systemic mycoses** are the most serious category of fungal infections. These are characterized by fungal growth in internal organs of the body (see Figure 34.5) and can be either primary or secondary infections. A *primary* infection occurs when an otherwise normal, healthy individual is infected with the fungal pathogen; these are rather uncommon. By contrast, a *secondary* infection occurs in a host that harbors a predisposing condition, such as antibiotic therapy or immunosuppression, that makes the individual more susceptible to infection.

Superficial and subcutaneous mycoses are for the most part easily treatable with topical drugs, including tolnaftate (applied topically), various azole drugs (applied either topically or orally), and griseofulvin, a relatively nontoxic drug that can be taken orally but passes through the bloodstream to the skin where it inhibits fungal growth. Chemotherapy against systemic fungal infections is more difficult because of issues with host toxicity (◀ Section 28.6). For example, one of the most effective antifungal agents, amphotericin B, is widely used to treat systemic fungal infections but can also reduce kidney function and have other unwanted side effects. Hence, effective treatment of the most serious of the mycoses is sometimes quite difficult.

Microbiology
Art Activity:
Table 34.1 Major
pathogenic
fungal diseases

Check Your Understanding

- Differentiate between superficial, subcutaneous, and systemic mycoses.
- What is a dimorphic fungus?
- Distinguish between a primary and a secondary fungal disease. Why do those suffering from HIV/AIDS often show secondary fungal infections of major internal organs?

34.2 Fungal Diseases: Mycoses

The two extremes of fungal infection are the superficial mycoses and the systemic mycoses. *Superficial mycoses* are quite common, and most individuals experience at least one in their lifetime. By contrast, *systemic mycoses* are far less common and primarily affect the elderly or otherwise immune compromised. As people age, cell-mediated immunity slowly declines as a result of surgeries, transplantations, immunosuppressive drug treatments for rheumatism and autoimmune diseases, and the onset of other conditions, such as pulmonary decline, diabetes, and cancer. Any of these can predispose the elderly to disease. Systemic mycoses also target those of any age whose immune systems have been impaired or destroyed, for example, by HIV/AIDS (◀ Figure 31.46). Systemic mycoses are thus diseases of *opportunistic pathogens*, microbes that cause disease only in those whose immune defenses can no longer fight them off (◀ Sections 25.4 and 31.15).

Superficial Mycoses

Table 34.1 listed some of the fungi that cause superficial mycoses; collectively, these pathogens are called *dermatophytes*. In general, superficial mycoses can be bothersome and often recurrent infections, but they are not serious health concerns. Fungi such as *Trichophyton* (Figure 34.1b) cause infections of the feet (athlete's foot) and other moist skin surfaces and are quite common (Figure 34.3a). These infections cause flaking and itchy skin and are easily transmitted by cells or spores of the pathogen present in contaminated shower stalls, gymnasium and locker room floors, contaminated shared articles such as towels or bed linens, or from close person-to-person contact.

Mastering
Microbiology
Art Activity:
Figure 34.5
Systemic
mycoses

Superficial mycoses can be treated with topical antifungal creams or liquid aerosols, although prophylactic application on a long-term basis may be necessary if constant exposure to the pathogen (for example, to *Trichophyton* on a locker room floor) is unavoidable.

Related surface mycoses include “jock itch,” an itchy infection of the groin, skin folds, or anus, and *ringworm* (Table 34.1). Despite the name, ringworm is a fungal infection, typically localized to the scalp or the extremities; the infection causes hair loss and inflammatory reactions (Figure 34.3b, c). These more severe superficial mycoses are usually treated topically with either miconazole nitrate or griseofulvin.

Subcutaneous Mycoses

Subcutaneous mycoses are fungal infections of deeper layers of skin than those of the superficial mycoses (Table 34.1). One disease in this class is *sporotrichosis* (Figure 34.4a), an occupational hazard of agricultural workers, miners, gardeners, and others who come into close and continual contact with the soil. The causative agent, *Sporothrix schenckii* (Figure 34.1d), is a ubiquitous soil saprophyte whose spores can enter through a cut or abrasion and infect subcutaneous tissues (Figure 34.4a). *Chromoblastomycosis* is due to pathogenic fungal growth in both surface (cutaneous) and subcutaneous skin layers, forming crusty, wartlike lesions on the hand (Figure 34.4b) or leg. The disease is primarily one of tropical and subtropical countries and occurs when the fungus becomes implanted under the skin from a puncture wound. Both sporotrichosis and chromoblastomycosis can be treated with oral administration of azoles.

Systemic Mycoses

Systemic fungal pathogens normally live in soil, and humans become infected by inhaling airborne spores that later germinate and grow in the lungs. From there the organism migrates throughout the body, causing deep-seated infections in the lungs and other organs and in the skin. In the United States, the three major systemic mycoses are, in order of decreasing incidence: histoplasmosis, coccidioidomycosis, and blastomycosis. Mortality from these is high, about 10%.

Figure 34.3 Superficial mycoses caused by *Trichophyton* spp. (a) Athlete's foot. (b) Ringworm on a child's face and (c) on an adult index finger. “Jock itch” (ringworm of the groin) is another common *Trichophyton* infection and can occur in females as well as males. *Trichophyton* is a filamentous fungus (see Figure 34.1b).

Figure 34.4 Subcutaneous mycoses. (a) Sporotrichosis, a subcutaneous infection caused by *Sporothrix schenckii*. (b) Chromoblastomycosis on the hand caused by the fungus *Phialophora verrucosa*. Chromoblastomycosis can also be caused by species of the fungal genera *Fonsecaea* and *Cladosporium*.

Histoplasmosis (Figure 34.5a) is caused by *Histoplasma capsulatum* (Figure 34.1e), and *coccidioidomycosis* (San Joaquin Valley fever, Figure 34.5d) is caused by *Coccidioides immitis* (Figure 34.1f). Histoplasmosis is primarily a disease of rural areas in midwestern states of the United States, especially in the Ohio and Mississippi River valleys, whereas coccidioidomycosis is generally restricted to the desert regions of the southwestern United States. In more tropical climates *blastomycosis*, caused by *Blastomyces dermatitidis*, is prevalent

(Figure 34.5b). *Paracoccidioidomycosis*, caused by the fungus *Paracoccidioides brasiliensis*, is primarily a subtropical disease with lesions forming on the face (Figure 34.5e) or other extremities.

Cryptococcosis (Figure 34.5c), caused by the dimorphic yeast *Cryptococcus neoformans* (Figure 34.1a), can occur in virtually any organ of the body and is the major mycosis seen in HIV/AIDS patients. The dimorphic yeast *Candida albicans* (Figure 34.1c) is often present as a minor component of the human microbiota. However, this fungus can cause a variety of diseases, including mild vaginal infections, more serious oral infections such as thrush (Figure 34.5f), and systemic infection of virtually any organ in those with HIV/AIDS. Like *Histoplasma* and *Coccidioides*, *Candida* and *Cryptococcus* are primarily opportunistic pathogens and rarely cause life-threatening infections except in immunocompromised individuals. An exception to this is *Candida auris*, a close relative of *Candida albicans* that has recently emerged as a deadly, multidrug-resistant threat in healthcare settings (see MicrobiologyNow in the Chapter 30 opener).

Our discussion transitions now from fungi to pathogenic parasites. Like fungi, parasites are eukaryotic microorganisms, but the pathogenic parasites typically attack quite different body tissues and organs than do the pathogenic fungi.

Check Your Understanding

- Give an example of a superficial, a subcutaneous, and a systemic mycosis.
- Why are systemic fungal pathogens called opportunistic?

(c) Cryptococcosis; yeast-form cells (stained red) in lung tissue. (d) Coccidioidomycosis; yeast-form cells (stained blue-black) in lung tissue. (e) Paracoccidioidomycosis lesions on the face. (f) Oral thrush. Masses of *Candida albicans* cells (yellow) line the back of the throat. See photomicrographs of cultures of the pathogens causing most of these mycoses in Figure 34.1.

II • Visceral Parasitic Infections

Visceral parasites include several pathogenic protozoa that cause diseases with symptoms ranging from mild gastroenteritis to lethal meningoencephalitis. These vicious pathogens are transmitted by various routes including contaminated food or water, environmental sources, or person-to-person contact.

Parasitism is a symbiotic relationship between two organisms, the parasite and the host (Chapters 23 and 24). The parasite derives essential nutrients from the host and may have little or no harmful effect on the host. However, in most cases, the parasite causes disease in the host. Many different phylogenetic groups of protists (Chapter 18) cause parasitic human diseases, and we examine some of the key ones here.

Parasitic infections can be either visceral—inducing vomiting, diarrhea, and other intestinal symptoms—or infections of blood and internal tissues. Some of the major diseases of human history, malaria for example, are parasitic diseases. We begin here with the visceral parasites and then consider blood and tissue parasites. Table 34.2 summarizes some major parasitic human diseases.

diseases

34.3 Amoebae and Ciliates: *Entamoeba*, *Naegleria*, and *Balantidium*

The genera *Entamoeba* and *Naegleria* belong to a large group of protists, the *Amoebozoa*, that move by extending lobe-shaped pseudopodia (◀ Section 18.8). Both parasites can cause serious—even fatal—infections, although *Naegleria* infections are very rare. *Balantidium* is a ciliated species of the alveolate group (◀ Section 18.4) and is mainly a disease of tropical countries.

Amebic Dysentery

Entamoeba histolytica (Figure 34.6) is transmitted by contaminated water or occasionally through contaminated food. *E. histolytica* is an anaerobe, and the organism’s *trophozoites* (the active, motile, feeding stage of the parasite) lack mitochondria. Like another common

Figure 34.6 *Entamoeba histolytica*, the causative agent of amebic dysentery. (a) Fluorescent photomicrograph of trophozoites of *E. histolytica* (blue) feeding on mouse intestinal cells (green); the trophozoites can be up to 60 μm in length. (b) Fluorescence photomicrograph of trophozoites of *E. histolytica* (green) ingesting human T cells (pink).

waterborne pathogen, *Giardia* (Section 34.4), the trophozoites of *E. histolytica* produce cysts, which are the means of transmission. Ingested cysts germinate to form amoebae that grow both on and in intestinal mucosa and can consume other available human cells (Figure 34.6b). This leads to breakdown of the intestinal epithelium, tissue invasion, and ulceration that triggers diarrhea and severe intestinal cramps.

With further growth, the amoebae can invade the intestinal wall—a condition called **dysentery**, characterized by intestinal inflammation, fever, and the passage of intestinal blood and mucus, which often leads to anemia. If the infection is not treated, *E. histolytica* can invade the liver, the lungs, and even the brain. Growth in these tissues causes abscesses that can be fatal. Nearly 100,000 people, primarily from developing countries where untreated sewage is allowed to enter surface waters, die each year from invasive amebic dysentery. Although no vaccine is available, *E. histolytica* amebiasis can be treated with a variety of drugs, and the host immune system plays a significant role in recovery, as well. However, the immune response to a primary *E. histolytica* infection does not confer immune memory (◀ Section 27.1), and reinfection is common.

Naegleria and *Balantidium* Infections

Naegleria fowleri can cause amebiasis, but in a much different form from that of *E. histolytica*. *N. fowleri* is a free-living amoeba present in soil and in runoff waters (Figure 34.7a). *N. fowleri* infections result from swimming or bathing in warm, soil-contaminated waters, such as warm springs or lakes and streams in summertime. *N. fowleri* enters the body through the nose and burrows directly into the brain. There the organism propagates, causing extensive hemorrhage and brain damage (Figure 34.7a), a condition called **primary amebic meningoencephalitis**. Diagnosis of an *N. fowleri* infection requires observation of the amoebae in cerebrospinal fluid. If a definitive diagnosis is made quickly, which is often not the case because the incidence of *Naegleria* meningoencephalitis is so low and the symptoms resemble those of meningitis, the drug amphotericin B can save the patient; untreated infections are almost always fatal (see also MicrobiologyNow on page 1059). Thus, although incidence of *Naegleria* meningoencephalitis is very low, mortality of untreated cases is near 100%, which makes this parasitic infection

extremely dangerous. In the United States only 36 cases of *Naegleria* meningoencephalitis were reported in the 10-year period between 2008 and 2018, and virtually all were from recreational waters.

Balantidium coli is a ciliated intestinal human and swine parasite that alternates between the trophozoite and cyst (Figure 34.7b) stages; only the cysts are infective. *B. coli* is the only known ciliated parasite of humans. Cysts, typically transmitted in feces-contaminated water, germinate in the colon and infect mucosal tissues, leading to symptoms that resemble those of amebiasis, for which the disease is sometimes mistaken. An infected patient usually experiences a spontaneous recovery or may become an asymptomatic carrier, continuously shedding *B. coli* cysts in the feces. Compared with amebiasis, *B. coli* infections are uncommon, and cases are rarely fatal.

Check Your Understanding

- Describe a scenario for contracting a *Naegleria* infection.

34.4 Other Visceral Parasites: *Giardia*, *Trichomonas*, *Cryptosporidium*, *Toxoplasma*, and *Cyclospora*

The protists *Giardia intestinalis* and *Trichomonas vaginalis* are flagellated anaerobic parasites that contain either mitosomes or hydrogenosomes in place of mitochondria (◀ Sections 18.1, 18.3); the parasites cause intestinal and sexually transmitted infections, respectively. The protist *Cryptosporidium* is transmitted primarily by contaminated water. *Cryptosporidium* is related to *Toxoplasma*, but *Toxoplasma* infection is primarily foodborne, as is infection by the pathogenic protist *Cyclospora*. We consider all five of these major human parasites here.

Giardiasis

Giardia intestinalis (also called *Giardia lamblia*) is typically transmitted to humans in fecally contaminated water and causes an acute gastroenteritis called *giardiasis*. The trophozoites of *Giardia* (Figure 34.8a, c) produce highly resistant cysts (Figure 34.8b) that function in transmission. Ingested cysts germinate in the small intestine to form trophozoites, and these travel to the large intestine where they attach to the intestinal wall and cause the symptoms of giardiasis: an explosive, foul-smelling, watery diarrhea; intestinal cramps; flatulence; nausea; weight loss; and malaise. The distinct odor and absence of fecal blood distinguish giardiasis from diarrheas due to bacterial or viral intestinal pathogens.

G. intestinalis causes a significant number of infectious disease outbreaks linked to contaminated drinking water in the United States (◀ Section 33.1). The thick-walled cysts are resistant to chlorine, and most outbreaks have been associated with water systems that used only chlorination as a means of water purification. Water subjected to proper clarification and filtration followed by chlorination or other disinfection (◀ Section 22.9) should be free of *Giardia* cysts. Most surface water sources (lakes, ponds, and streams) contain *Giardia* cysts, as beavers and muskrats are carriers of this pathogen. This is why untreated surface waters should never be directly ingested but instead should be filtered and disinfected with iodine or chlorine or, alternatively, filtered and boiled. The drugs quinacrine, furazolidone, and metronidazole are useful for treating acute giardiasis.

Trichomoniasis

Trichomonas vaginalis (Figure 34.9) causes a sexually transmitted infection, *trichomoniasis*. *T. vaginalis* does not produce resting cells or cysts, and as a result, *Trichomonas* transmission is typically from

Figure 34.8 *Giardia*. (a) Fluorescently stained cells of *Giardia intestinalis*. (b, c) Scanning electron micrographs of (b) a giardial cyst and (c) a motile *G. intestinalis* trophozoite. The trophozoite is 15 μm long and the cyst about 11 μm wide.

person to person through sexual intercourse. However, unlike most sexually transmitted bacterial pathogens, cells of *T. vaginalis* can survive for several hours on moist surfaces and up to a day in urine or semen. Hence, in addition to disease transmission by intimate contact, trichomoniasis can be transmitted by contaminated fomites, such as toilet seats, sauna benches, and towels.

T. vaginalis infects the vagina in women, the prostate and seminal vesicles of men, and the urethra of both males and females. Trichomoniasis is often asymptomatic in males. By contrast, trichomoniasis in females is characterized by a yellowish vaginal discharge that causes a persistent vaginal itching and burning. The infection is more common in females; surveys have shown that up to 25% of sexually active women are infected with *T. vaginalis*, whereas only about 5% of sexually active males are infected (conditions in the male are less conducive to colonization by the protist). Trichomoniasis is diagnosed by observation of the motile protists in a wet mount of fluid discharged from the patient (Figure 34.9b). The antiprotozoal drug metronidazole is effective for treating trichomoniasis.

Cryptosporidiosis, Toxoplasmosis, and Cyclosporiasis

Cryptosporidium, *Toxoplasma*, and *Cyclospora* are genera of parasitic coccidia, which group among the alveolates (◀ Section 18.4). These parasites are transmitted to humans in feces-contaminated food or water and can trigger serious bouts of diarrhea, or in the case of *Toxoplasma*, serious internal organ damage.

Cryptosporidium parvum infects many warm-blooded animals, in particular cattle. The organism forms small, coccoid cells that invade and grow intracellularly in mucosal epithelial cells of the stomach and intestine (Figure 34.10a), resulting in the gastrointestinal illness *cryptosporidiosis*. *C. parvum* produces thick-walled, highly resistant cysts called *oocysts* (Figure 34.10b), which enter

water from the feces of infected animals. The infection is then transmitted to other animals and humans when they consume the feces-contaminated water.

Cryptosporidium oocysts are highly resistant to chlorine, and because of this, sedimentation followed by filtration is the only reliable way to remove them from water supplies. In an average year, *Cryptosporidium* is responsible for the majority of recreational waterborne disease outbreaks in the United States (Chapter 33) but is only occasionally associated with drinking water outbreaks. Nevertheless, *C. parvum* was responsible for the largest single outbreak of disease associated with drinking water ever recorded in the United States. In the spring of 1993, one-quarter of the population of Milwaukee, Wisconsin (USA), developed cryptosporidiosis from consuming water from the municipal water supply. Heavy spring rains and runoff from cattle manure on farmlands had drained into Lake Michigan, the water supply for the city, and overburdened the water purification system, leading to contamination by *C. parvum*.

In otherwise healthy individuals, cryptosporidiosis typically causes only a mild, self-limiting diarrhea, making treatment unnecessary. However, individuals with impaired immunity, such as that caused by HIV/AIDS, or the very young or old can develop serious complications from a *C. parvum* infection. For example, cryptosporidiosis is the leading cause of pediatric diarrhea worldwide, and it is responsible for nearly 9% of fatalities due to infectious disease in children. The primary laboratory diagnostic method for cryptosporidiosis is the demonstration of oocysts in feces (Figure 34.10b). Immunological and molecular tools are also available for more precise identification of strains of the pathogen when such tracking is necessary.

Like *C. parvum*, the parasite *Cyclospora cayetanensis* forms oocysts and causes a mild to occasionally severe gastroenteritis called *cyclosporiasis*. However, unlike *C. parvum*, *C. cayetanensis* is primarily transmitted by feces-contaminated, fresh foods rather than by contaminated water. Most cases of cyclosporiasis have been linked to

Figure 34.10 *Cryptosporidium parvum*. (a) Light micrograph of intracellular trophozoites of *C. parvum* (arrows) embedded in human gastrointestinal epithelium. The trophozoites are about 5 μm in diameter. (b) Thick-walled *C. parvum* oocysts are about 3 μm in diameter in this fecal sample.

contaminated fruits or vegetables. A major outbreak in the United States in the summer of 2013 was linked to packaged lettuce (◀ Section 33.7). Another major *C. cayetanensis* outbreak in the United States occurred from May to August 2018, but in this incident, the outbreak was linked to multiple food items. Prepackaged vegetable trays containing broccoli, cauliflower, and carrots sold at a chain of convenience stores, and salads containing carrots, romaine lettuce, spinach, and kale sold at a fast food chain, were among the products that resulted in 2299 cases of cyclosporiasis.

Toxoplasmosis is caused by *Toxoplasma gondii* (Figure 34.11). This parasite infects many warm-blooded animals, and roughly half of all adults in the United States are infected but asymptomatic because their immune system keeps the organism in check. *T. gondii* is typically transmitted to humans in the form of cysts present in undercooked beef, pork, or lamb; by direct infection from cats, which are major carriers of *T. gondii*; and occasionally from contaminated water. A key step in the *T. gondii* life cycle is completed in felines, and thus they are obligate hosts; humans and other animals are only accidental hosts. Most transmission to humans is thus probably from cats.

Toxoplasmosis can be associated with mild to severe symptoms. When cysts of *T. gondii* are ingested, they germinate in and penetrate the wall of the small intestine. From this initial infection, symptoms can be inapparent or apparent but indistinguishable from those of a mild case of influenza (headache, muscle ache, general malaise). However, in some infected persons, *T. gondii* cysts migrate from the small intestine and circulate throughout the body. Subsequently, the parasite can penetrate nerve cells and infect tissues of the brain and eyes, a pathology that has been linked to altered behaviors, such as increased risk taking, obsessive-compulsive disorder, and schizophrenia. Although disease symptoms in healthy adults are uncommon, in immunocompromised individuals, damage to the eyes, brain, and other internal organ systems occurs with higher frequency. In addition, a first-time infection with *T. gondii* in expectant mothers can lead to congenital infection and birth defects in newborns. Thus, pregnant women who have not been in contact with cats should avoid cats until after giving birth.

Figure 34.11 *Toxoplasma*. Tachyzoites (rapidly growing cells) of *Toxoplasma gondii*, an intracellular parasite. In this transmission electron micrograph, the tachyzoites (arrows) form a cystlike structure in a host cardiac cell. The *Toxoplasma* tachyzoites are 4–7 μm long. For a photo of *T. gondii* sporozoites (the infective phase of the parasite's life cycle), see Figure 18.11b.

Check Your Understanding

- What symptoms of giardiasis would suggest that your gastroenteritis was not due to a bacterial pathogen?
- How does one contract a case of trichomoniasis? A case of toxoplasmosis?
- What is unusual about the oocysts of *Cryptosporidium* that facilitates its transmission by a water route?

III • Blood and Tissue Parasitic Infections

Parasitic protozoa and helminths that infect the blood and other tissues cause some of the most prevalent and devastating diseases in the world, many of which are endemic in tropical and subtropical regions. Malaria is the most prevalent parasitic disease worldwide.

Several human parasites infect organs and tissues other than the gastrointestinal tract and are typically transmitted by insect vectors. We begin our consideration of these with malaria, the most devastating and widespread of parasitic diseases and one that remains a major global health problem today.

34.5 *Plasmodium* and Malaria

Malaria is caused by protists of the alveolate group (◀ Section 18.4). Several species of the protozoal genus *Plasmodium* cause malarial diseases in warm-blooded hosts; up to 250 million people worldwide contract malaria annually and about 600,000 die from the disease. Malaria is thus one of the most common causes of death worldwide from infectious disease and certainly the most prevalent of protozoal diseases.

In malaria, the complex parasite life cycle requires a mosquito vector. Four species of *Plasmodium*—*P. vivax*, *P. falciparum*, *P. ovale*, and *P. malariae*—cause most human malaria. The most widespread disease is caused by *P. vivax*, whereas the most serious disease is caused by *P. falciparum*. Humans are the only reservoirs for these four species. The protists carry out part of their life cycle in the human and part in the female *Anopheles* mosquito, the only vector that transmits *Plasmodium* spp. The vector spreads the protist from person to person.

Malarial Life Cycle

The life cycle of *Plasmodium* is complex and involves a number of stages (Figure 34.12). First, the human host is infected by plasmodial *sporozoites*, small, elongated cells produced in the mosquito that localize in the salivary gland of the insect. The mosquito (Figure 34.12 inset) injects saliva containing the sporozoites into the human when obtaining a blood meal. The sporozoites travel to the liver where they infect liver cells. Here, some *Plasmodium* species, including *P. vivax*, may assume a dormant *hypnozoite* form for weeks to years, but eventually all species of the parasite replicate and become enlarged in a stage called the *schizont* (see Figure 34.13b). The schizonts then segment into a number of small cells called

Mastering

Art Activity:
Figure 34.12 The
life cycle of
Plasmodium

Figure 34.12 The life cycle of *Plasmodium*. The life cycle of *Plasmodium* requires both an endothermic (warm-blooded) host—in this case, a human—and the mosquito vector. Transmission of the protist to and from the human host is done by the bite of an *Anopheles gambiae* mosquito (inset) or certain other *Anopheles* species. Mosquito photo courtesy of CDC/PHIL, J. Gathany.

merozoites, which exit the liver into the bloodstream. Some of the merozoites then infect erythrocytes (red blood cells).

The plasmodial life cycle in erythrocytes proceeds with repeated division, growth, and release of merozoites (Figure 34.13), resulting in destruction of the host red blood cells. Plasmodial growth in erythrocytes typically repeats at synchronized intervals of 48 h. During this period, the host experiences the defining clinical symptoms of malaria: chills followed by fever of up to 40°C (104°F). The chill–fever pattern coincides with the release of merozoites from the erythrocytes during the synchronized reproduction cycle. Vomiting and severe headache may accompany the chill–fever cycles, and over the longer term, characteristic symptomatic malaria can alternate

with asymptomatic periods. Because of the destruction of red blood cells and consumption of hemoglobin by the parasite, malaria typically causes anemia, enlargement of the spleen, and fatigue.

Plasmodial merozoites eventually develop into *gametocytes*, cells that infect only mosquitoes. The gametocytes are ingested when an *Anopheles* mosquito takes a blood meal from an infected person, and they mature within the mosquito into *gametes*. Two gametes fuse to form a *zygote*, and the *zygote* migrates by amoeboid movement (◀ Section 18.8) to the outer wall of the insect’s intestine where it enlarges and forms several *sporozoites*. These are released and reach the salivary gland of the mosquito, from where they can be introduced into another person during a subsequent bite, and the cycle begins anew (Figure 34.12).

Epidemiology, Diagnosis, Treatment, and Control

Anopheles mosquitoes (Figure 34.12 inset) live predominantly in the tropics and subtropics and are the vector for malaria. Diagnosis of malaria requires the identification of *Plasmodium*-infected erythrocytes in blood smears (Figure 34.13a). Fluorescent nucleic acid stains, nucleic acid probes, PCR assays, and various antigen-detection methods (Chapter 29) are also used to verify *Plasmodium* infections or to differentiate between infections with various *Plasmodium* species.

Treatment of malaria is traditionally accomplished with quinine-based therapeutics, such as *chloroquine*. Chloroquine kills merozoites within red blood cells but does not kill sporozoites. The related drug *primaquine* eliminates sporozoites of *P. vivax* and *P. ovale* that may remain in liver cells. Thus treatment with both chloroquine and primaquine effectively cures malaria in some cases. More recently, the antimalarial drug *artemisinin*, derived from the wormwood plant originally but now made by genetically engineered yeast strains (◀ Section 12.11 and Figure 12.37), has provided more

Mastering

When released from the schizont, the merozoites infect erythrocytes (Figure 34.12). Red blood cells about 8 μm in diameter; merozoites are 2–3 μm in diameter.

reliable elimination of the parasite, and its use has become widespread. However, in some individuals, malaria recurs years after the primary infection when a few sporozoites not eliminated from the liver release a new generation of merozoites. Quinine- and artemisinin-resistant strains of *Plasmodium* are now widespread, especially in Southeast Asia where the prevalence of malaria is extremely high. As a result, *combination therapy*, in which the malaria patient is treated with several antimalarial drugs at once, is now a common form of treatment.

Malaria can be controlled by either draining swamps and other mosquito breeding areas or by eliminating the vector with insecticides. Together, these measures have all but eliminated malaria in the United States, with most cases being imported. Several malaria vaccines are also in development, including synthetic peptide vaccines, recombinant particle vaccines, and DNA vaccines (◀ Sections 12.8 and 28.3), but thus far no highly effective and reliable malaria vaccine has emerged for use in mass vaccination programs.

Check Your Understanding

- Which stages of the *Plasmodium* life cycle occur in humans, and which in the mosquito?
- What are the natural reservoirs and vectors for *Plasmodium* species? How can malaria be prevented or eradicated?
- What drugs are used to treat malaria?

34.6 Leishmaniasis, Trypanosomiasis, and Chagas Disease

Parasites of the genera *Leishmania* and *Trypanosoma* are transmitted by bloodsucking insect vectors. These parasites are *hemoflagellates*, organisms that reside in blood or related tissues such as the liver and spleen, and they cause major human diseases, primarily in tropical and subtropical countries.

Leishmaniasis

Leishmaniasis is a parasitic disease of various forms caused by species of the genus *Leishmania*, a flagellated protozoan related to *Trypanosoma*. The disease is transmitted to humans by a bite from the sand fly (Figure 34.14a). *Cutaneous leishmaniasis*, caused by either *L. tropica* or *L. mexicana*, is the most common form of leishmaniasis. Following transmission of the parasite in a blood meal (Figure 34.14a, b), the parasite infects and grows within human macrophage cells (◀ Section 26.4), leading eventually (weeks or months later) to the formation of a small nodule on the skin. The nodule then enlarges to form an ulcerous skin lesion (Figure 34.14c) that contains active parasites. In the absence of secondary bacterial infections, which are common if the ulcerated tissue is left open, the lesions heal spontaneously over a period of several months but can leave a permanent scar.

Leishmaniasis has historically been treated with injections of pentavalent antimony (Sb^{5+}) compounds. Although the mode of action of these compounds is unknown, it is thought that Sb^{5+} in some way stimulates or activates the immune response to better attack the *Leishmania* parasites. At present, however, many *Leishmania* species are resistant to antimony compounds, but a variety of other drugs

Figure 34.14 Leishmaniasis. (a) The sand fly (genus *Phlebotomus*) transmits leishmaniasis in a blood meal. (b) *Leishmania* spp. are flagellated protozoans and the cause of leishmaniasis. (c) Cutaneous leishmaniasis showing an open ulcer on the hand.

are available for treating resistant cutaneous forms of the disease. Cutaneous leishmaniasis exists in over 88 tropical and subtropical countries, with an estimated prevalence of about 1 million cases worldwide. Occasional reports of the disease are documented in the United States, most often in the state of Texas.

Visceral leishmaniasis is caused by *Leishmania donovani* and is the most severe form of the disease. In visceral leishmaniasis, the parasite travels from the site of infection to internal organs, in particular the liver, spleen, and bone marrow. If left untreated, the visceral disease is almost always fatal. Common symptoms of visceral leishmaniasis include a cycling of fever and chills, a slow reduction in both red and white blood cell numbers, and significant enlargement of the spleen and liver that can lead to pronounced distention of the abdomen. Treatment includes injections of antimony (as for the cutaneous disease), long periods of bed rest, and blood transfusions in acute cases if blood cell counts become dangerously low. Estimates of visceral leishmaniasis prevalence worldwide are about 300,000, causing about 20,000 deaths annually. In addition, because the range of the sand fly is already broad and is increasing with climate change and tropical and subtropical deforestation, it is estimated that worldwide nearly 400 million people (over 5% of the world's humans) could be at risk of some form of leishmaniasis.

Trypanosomiasis and Chagas Disease

Flagellated protozoans of the genus *Trypanosoma* (◀ Section 18.3) cause two related forms of **trypanosomiasis**. Two subspecies of *Trypanosoma brucei* native to Africa, *T. brucei gambiense* and *T. brucei rhodesiense*, cause *African trypanosomiasis*, better known as *African sleeping sickness*. The species *T. cruzi* causes *Chagas disease*, also known as *American trypanosomiasis*. As discussed below, both forms of trypanosomiasis are transmitted by the bite of specific insect vectors.

Sleeping sickness is transmitted by the tsetse fly (genus *Glossina*; Figure 34.15a), an insect similar in dimensions to a housefly and native only to tropical regions of Africa; sleeping sickness is therefore endemic only in countries of sub-Saharan Africa. The disease begins

Figure 34.15 African trypanosomiasis and Chagas disease. (a) The tsetse fly (genus *Glossina*), the vector of African trypanosomiasis. The insect is about 1 cm in length. (b) Two cells of *Trypanosoma brucei* (arrow), the causative agent of African sleeping sickness (African trypanosomiasis), in a blood smear. (c) The reduviid (“kissing”) bug (*Triatoma infestans*), the vector for Chagas disease (American trypanosomiasis). The insect is about 2 cm in length. (d) A cell of *Trypanosoma cruzi* (arrow), the causative agent of Chagas disease, in a blood smear.

with intermittent fever, headache, and malaise. The trypanosome parasite multiplies in the blood (Figure 34.15b) and later infects the central nervous system and grows in cerebrospinal fluid. Neurological symptoms soon begin, with the primary symptom being disrupted sleep patterns marked by random periods of extreme lethargy and drowsiness. This is due to the parasite producing the aromatic alcohol *tryptophol*, a derivative of the amino acid tryptophan, which triggers a sleep response. Without treatment, the infection gradually progresses to a coma, multiple organ failure, and eventually death after months or years. A variety of anti-trypanosomal drugs are available for treating sleeping sickness; some are used primarily for treating the blood infection while others are used if the disease has progressed to the neurological stage. About 10,000 new cases of sleeping sickness are reported annually, but most cases are thought to go unreported.

Chagas disease, named for its discoverer, is caused by *T. cruzi*, a close relative of *T. brucei*, and is transmitted by the bite of the reduviid bug, or “kissing bug” (Figure 34.15c, d). Chagas disease mainly occurs in Latin American countries. The parasite affects several organs including the heart, gastrointestinal tract, and central nervous system, causing inflammatory reactions and tissue destruction. The acute illness is usually self-limiting, but if chronic illness develops, heart damage is significant and is the eventual cause of premature death. About 20,000 deaths due to Chagas disease occur annually in endemic Latin American countries. The disease is treated with anti-trypanosomal drugs, such as benznidazole, but currently no vaccines are available for prevention of African or American trypanosomiasis.

Schistosomiasis

Check Your Understanding

- How are trypanosome diseases similar to malaria and how do they differ?
- How do the symptoms of cutaneous and visceral leishmaniasis differ?
- How are sleep patterns altered in cases of African trypanosomiasis?

34.7 Parasitic Helminths: Schistosomiasis and Filariases

Some parasitic diseases are caused by helminths, tiny worms that burrow into the human host and cause debilitating diseases and death. We consider the most widespread of these, schistosomiasis, along with brief coverage of other, less common helminth infections.

Schistosomiasis

Schistosomiasis, also called *snail fever*, is a chronic parasitic disease caused by species of trematodes (flatworms) of the genus *Schistosoma*; the major species is *S. mansoni* and adult worms can be up to a centimeter in length (Figure 34.16a). The life cycle of the parasite requires both snails and humans (or other mammals) as hosts. Schistosome eggs (Figure 34.16b) released into a freshwater aquatic environment hatch to generate *miracidia*, the form of the worm that

Figure 34.16 Schistosomiasis. (a) Adult worm of *Schistosoma mansoni*; the worm is about 1 cm in length. (b) An *S. mansoni* egg, about 0.15 mm long. The lateral spur (bottom right) is characteristic of the eggs of this species. (c) Fluorescently stained cercaria, the infective form of *S. mansoni*. From the head (top) to the bifurcated tail is about 1 mm. (d) Cercarial infection of the forearm. Five infection sites (arrows) are apparent.

infects snails. In the snail, miracidia are transformed into *cercariae* (Figure 34.16c), the motile stage of the parasite that is released and infects humans.

A cercaria burrows into the skin, leaving a small surface lesion (Figure 34.16d), and then migrates to the lungs and liver; in the process, the worm establishes a long-term infection in the blood vessels. From the liver, the parasite infects the bladder, kidneys, and urethra, and the female worm produces large numbers of eggs. The eggs are shed in the urine and also pass through the intestinal wall and are shed in the feces. Large egg masses also become trapped along with fluids in the bladder, liver, and other organs, triggering an inflammatory response and severe distention of the abdomen, a condition commonly seen in infected children (Figure 34.17a). Other symptoms include bloody urine, diarrhea, and abdominal pain. Eggs as well as adult worms can live in the body for years, causing chronic symptoms that can last from youth into adulthood.

Schistosomiasis is a disease of tropical countries, primarily those in Africa, but some cases also occur in subtropical countries, including those of Latin America and the Caribbean region. Poverty, poor sanitation, and land use changes are typically associated with widespread infection. Although there is no vaccine, schistosomiasis is treated with the drug praziquantel, and the diagnosis is made relatively easily by assessing symptoms and observing parasite eggs in the urine and feces. Mortality from schistosomiasis is low, about 0.1%, but schistosomiasis is second only to malaria in terms of total parasitic infections worldwide. In 2017, over 220 million cases of the disease were treated, and many others probably went untreated.

Filariases

Several other parasitic helminth infections are known, and chief among these are the *filariases*, infections by parasitic nematodes (roundworms). Unlike the schistosomiasis parasite, these worms are clearly macroscopic in the adult stage (several centimeters in length, depending on the filariasis).

Bancroft's filariasis (also called elephantiasis) is a chronic infection of the lymphatic system by the roundworm *Wuchereria bancrofti*. The worm is transmitted to humans as tiny *microfilariae* in a mosquito

bite. Once in the host, microfilariae develop into adult worms and these interrupt lymph flow, leading to massive accumulation of fluids (edema), especially in the lower extremities. Fluid accumulation in lower regions of the body can cause severe edema of the legs (Figure 34.17b). Over 120 million people in the tropics suffer from *W. bancrofti* infection, but the microfilarial stage of the disease is readily treatable with antihelminthic drugs (◀ Section 28.6) or the drug diethylcarbamazine, which kills both microfilariae and adult worms. Even simpler treatment may be available by administering antibacterial antibiotics. Although the worm itself is not sensitive to these drugs, the worm harbors an endosymbiotic bacterium, *Wolbachia* (*Alphaproteobacteria*, ▶ Sections 16.1, 32.5), which is killed by various antibiotics. If *Wolbachia* is eliminated by antibiotic treatment, the worms die, and so antihelminthic treatments often include antibiotics such as doxycycline (▶ Section 28.5) to accelerate the removal of worms from the patient.

Onchocerciasis (also called *river blindness*) is due to a chronic infection by the large parasitic roundworm *Onchocerca volvulus* (Figure 34.18a). Humans are the only known host for this parasite, but biting flies are vectors when they become infected with microfilariae in a blood meal and transmit them to uninfected humans. Blackflies of the genus *Simulium* are the major means of transmission. The microfilariae invade the cornea, and from there the iris and retina, triggering an inflammatory response that causes scarring and partial to total loss of vision. *O. volvulus* infection is second only to trachoma (▶ Section 31.13) as a cause of infectious blindness. It is estimated that about 20 million people are infected with this parasite, primarily in equatorial Africa.

The disease *trichinosis* (also called *trichinellosis*) is caused by species of the parasitic roundworm *Trichinella* (Figure 34.18b). This worm commonly infects the muscle tissues of wild mammals and can occasionally infect domestic animals, especially swine; about 20 cases of human trichinosis are reported in the United States each year, usually from the consumption of undercooked wild game or undercooked pork. Human infection with *Trichinella* begins when worm larvae enter intestinal mucosal cells, leading to either an asymptomatic condition or mild gastroenteritis. As the larvae mature and reproduce, new larvae circulate throughout the body and lead to systemic inflammatory reactions such as malaise,

Figure 34.17 Symptoms of parasitic helminth infections. (a) Schistosomiasis in a small child. The swollen abdomen from the accumulation of fluids and worm eggs is characteristic of the infection. (b) Bancroft's filariasis (elephantiasis). The swollen legs are the result of edema from infection of lymph tissues by the roundworm *Wuchereria bancrofti*.

Figure 34.18 The roundworms of river blindness and trichinosis. (a) A worm larva of *Onchocerca volvulus*, the causative agent of river blindness. The microfilarial worm is about 0.3 mm long, but adult worms can be several centimeters in length. (b) Cysts of *Trichinella spiralis* containing worm larvae in muscle tissue. Unlike the much larger *O. volvulus*, adult worms of *T. spiralis* are just a few millimeters long.

facial swelling, and fever. Untreated cases of trichinosis can progress to more severe organ-specific symptoms including heart damage, encephalitis, and even death. However, if properly diagnosed (usually by immunological assays on biopsied muscle tissue), trichinosis is treatable with a variety of drugs, in particular the benzimidazole class of antihelminthics.

Check Your Understanding

- How does the pathogen that causes schistosomiasis differ from all other pathogens considered in this chapter?
- From what source are most cases of human trichinosis contracted?

Go to **Mastering Microbiology** for videos, animations, practice tests, and more.

CHAPTER REVIEW

I • Fungal Infections

- 34.1** Fungi include the molds and yeasts, and some fungi are dimorphic, meaning that both mycelial and yeast phases can occur. Superficial, subcutaneous, and systemic mycoses refer to fungal infections of the skin surface, skin subsurface, and internal organs, respectively. Fungal infections can be mild or serious, depending on the health and immune status of those infected.

Q What are the major mechanisms through which fungi cause disease?

- 34.2** Superficial mycoses such as athlete's foot or jock itch are mild and easily treatable, whereas subcutaneous mycoses, such as sporotrichosis, or especially systemic mycoses, such as histoplasmosis, are more difficult to treat effectively. The ability of fungi that cause systemic mycoses to infect internal organs makes these pathogens particularly dangerous to the elderly or those otherwise immune compromised.

Q How are systemic mycoses characterized? What is the difference between a primary and a secondary infection caused by systemic mycoses?

II • Visceral Parasitic Infections

- 34.3** The genera *Entamoeba* and *Naegleria* are amoebic human parasites that cause gastrointestinal and brain infections, respectively. *Entamoeba* is transmitted in feces-contaminated waters, whereas *Naegleria* inhabits warm, soil-contaminated waters. *Balantidium* is a ciliated intestinal parasite transmitted by feces-contaminated water.

Q If you were to contract one or the other, which would you rather have, an *Entamoeba* infection or a *Naegleria* infection, and why?

- 34.4** The protists *Giardia intestinalis* and *Cryptosporidium parvum* are major waterborne pathogenic parasites, whereas *Toxoplasma gondii* is primarily a foodborne or cat-transmitted parasite, and *Trichomonas vaginalis* is a sexually transmitted parasite. The pathogenic parasite *Cyclospora* is primarily transmitted by fresh vegetables such as lettuce and spinach contaminated with animal feces. None of these parasites causes life-threatening diseases in otherwise healthy individuals, although *T. gondii* can trigger severe and even fatal

infections in immunocompromised hosts and can cross the placenta to cause serious congenital infections.

Q In contrast to disease caused by *Trichomonas*, what do giardiasis and cryptosporidiosis have in common?

III • Blood and Tissue Parasitic Infections

- 34.5** Infections with *Plasmodium* spp. cause malaria, a widespread, mosquito-transmitted disease of the blood that causes significant morbidity and mortality in tropical and subtropical regions of the world. Malaria is treatable with quinine-based drugs and artemisinin but is not yet preventable by vaccination.

Q Malaria symptoms include chills followed by fever. These symptoms are related to activities of the pathogen. Describe the growth stages of *Plasmodium* spp. in the human host and relate them to the chill-fever pattern.

- 34.6** Leishmaniasis is a parasitic disease caused by *Leishmania* species; the cutaneous form of the disease is most common. *Trypanosoma brucei* causes African trypanosomiasis (African sleeping sickness), while the related species *Trypanosoma cruzi* causes Chagas disease (American trypanosomiasis). All of these diseases are transmitted by the bite of specific insect vectors.

Q Contrast leishmaniasis with the two types of trypanosomiasis in terms of causative agents, symptoms, and transmission vectors.

- 34.7** Schistosomiasis is a prevalent parasitic disease caused by a microscopic worm, *Schistosoma mansoni*. The life cycle of the parasite requires both snails and mammals. The worm infects the liver and kidneys and produces large egg masses that accumulate in the body, leading to systemic inflammation and abdominal distention. Other parasitic worm diseases, such as elephantiasis and river blindness, also leave readily visible signs of infection. Trichinosis is caused by a roundworm that infects the intestine and muscle tissues and is a threat from the consumption of undercooked pork or wild game.

Q In what unusual way does the parasite *Schistosoma mansoni* enter the body to cause infection? Are there any physical signs of infection when it occurs?

APPLICATION QUESTIONS

1. Malaria eradication has been a goal of public health programs for at least 100 years. What factors preclude our ability to eradicate malaria? If an effective vaccine was developed, could malaria be eradicated?
2. In terms of public health, what is a common problem that unites many of the visceral parasitic infections covered in this chapter? How could this problem be attacked? Why are these diseases rare in developed countries?
3. Explain why the diseases malaria, leishmaniasis, and trypanosomiasis are primarily diseases of tropical regions. How could humans be affecting the future geographical ranges of these diseases?
4. Explain why systemic fungal infections are typically seen only in certain individuals even though many people have contact with the pathogen, whereas an outbreak of giardiasis affects virtually everyone that has come in contact with the pathogen.

CHAPTER GLOSSARY

Dysentery a disease characterized by intestinal ulceration and inflammation, fever, and the passage of diarrhea containing intestinal blood and mucus

Leishmaniasis a disease of the skin or viscera caused by infection with species of a parasitic flagellated protozoan, *Leishmania*

Malaria a disease characterized by recurrent episodes of fever and anemia; caused by species of the protist *Plasmodium*, usually transmitted between mammals through the bite of the *Anopheles* mosquito

Mycosis (plural, mycoses) any infection caused by a fungus

Primary amebic meningoencephalitis the invasion, inflammation, and destruction of brain tissue by the amoeba *Naegleria fowleri* or a variety of other amoebic parasites

Schistosomiasis a chronic disease caused by a parasitic worm that leads to internal organ damage and accumulation of fluids and worm egg masses

Subcutaneous mycoses fungal infections of deeper layers of skin

Superficial mycoses fungal infections of the surface layers of skin, hair, or nails

Systemic mycoses fungal growth in internal organs of the body

Trypanosomiasis any parasitic disease of the blood and internal tissues caused by species of the flagellated protozoan *Trypanosoma*; African sleeping sickness and Chagas disease are two major trypanosomiasis

Fagg and Michael J. Ferris, Montana State University; **19.17c:** Gerard Muyzer and Abdelaziz Belila; **19.20a:** Jizhong (Joe) Zhou, Zhili He, and Joy Van Nostrand; **19.22:** Vaughn Iverson and Ginger Armbrust; **19.27:** Trent R. Northen, Mia Jones; **19.33:** Niels Peter Revsbech; **19.34a, b:** The figure data and components were generated by Dr. Klaus Koren (Department of Bioscience, University of Aarhus) and Dr. Michael Kühl (Department of Biology, University of Copenhagen) with technical assistance of Sofie Lindegaard Jakobsen (Department of Biology, University of Copenhagen); **19.34c:** Philippe Laissue; **19.38:** Colin Murrell; **19.39b, d:** Jennifer Pett-Ridge, Peter K. Weber; **19.39c:** Peter K. Weber; **19.40:** Eva Heinz and Matthias Horn; **19.41a:** Michael Wagner, Kilian Stöcker, and Holger Daims; **19.41b, c:** Michael Wagner, Per Nielsen, and Natuscka Lee.

Chapter 20 Chapter Opener: Belinda Ferrari; **20.1:** Hans Paerl, University of North Carolina at Chapel Hill; **20.4a:** Frank Dazzo; **20.4b:** Thomas D. Brock; **20.4c:** Cindy E. Morris, INRA, Centre de Recherche d'Avignon, France. Previously published in *Applied and Environmental Microbiology* 63:1570-1576; **20.4d:** C. T. Huang, Karen Xu, Gordon McFeters, and Philip S. Stewart; **20.5:** Courtesy of Marilyn B. Vogel and David J. Des Marais; **20.6:** Anna Depetris and Tom Ian Battin; **20.7:** The SEM picture was taken by Maria Arias-Andres and Reingard Rossberg in the frame of the Leibniz SAW-project 'MikrOMIK' (SAW-2014-IOW-2); **20.8a:** Jesse Dillon and David A. Stahl; **20.8b:** David M. Ward; **20.9a:** J. M. Sanchez, J. Lidel Lope and Ricardo Amils; **20.9b:** W. Inskeep; **20.10:** Andreas Teske and Markus Huettel; **20.11b:** Michael T. Madigan; **20.13:** Jayne Belnap; **20.14:** Winai Tepsuttinun/Fotolia; **20.15a:** Terry C. Hazen; **20.15b:** Esta van Heerden; **20.17:** Luis R. Comolli; **20.19b:** Thomas D. Brock; **20.20:** Yuriy Brykaylo/Alamy Stock Photo; **20.21:** Otis Brown and Robert Evans, NASA; **20.23a:** US Coast Guard Photo/Alamy Stock Photo; **20.23b:** NASA; **20.24:** David L. Valentine; **20.25:** Sallie Chisholm, **inset:** Alexandra Z. Worden and Mya E. Breitbart, Scripps Institution of Oceanography, University of California at San Diego; **20.27a:** Hans W. Paerl, University of North Carolina at Chapel Hill; **20.27b:** Alexandra Z. Worden and Brian P. Palenik, Scripps Institution of Oceanography, University of California at San Diego; **20.28:** Vladimir Yurkov; **20.30:** Daniela Nicastro; **20.32:** Jed Fuhrman/Matt Sullivan, **inset:** Jennifer R. Brum/Matt Sullivan; **20.34:** Kathryn Kauffman, Nicki Watson, Martin Polz; **20.35:** Photographer: Nick Verola; **20.38:** Hideto Takami, Japan Marine Science and Technology Center, Kanagawa, Japan; **20.39a:** Doug Bartlett; **20.40a:** Andreas Teske; **20.42:** Sea Research Foundation (SRF) and the Ocean Exploration Trust (OET)/NOAA; **20.44:** Robert D. Ballard/Woods Hole Oceanographic Institution; **20.45:** Deborah Kelley, University of Washington; **20.46:** Christian Jeannot; **20.47:** Carl Wirsén/Woods Hole Oceanographic Institution.

Chapter 21 Chapter Opener: Rebecca Albright; **21.3:** Evan Solomon; **21.5:** David L. Valentine; **21.8a:** John A. Breznak; **21.8b, c:** Monica Lee and Stephen H. Zinder; **21.13a:** Eye of Science/Science Source; **21.13b:** Lars Peter Nielsen; **21.17:** J. M. Sanchez, J. Lidel Lope and Ricardo Amils; **21.18a-g:** David Emerson; **21.19a:** Clara Chan and Deborah Powell, UD Biomaging Center; **21.19b:** Shingo Kato, Clara Chan, and Deborah Powell, UD Biomaging Center; **21.20a:** Jörg Bollmann; **21.20b:** M. L. Cros Miguel and J. M. Fortuño Alós; **21.21a:** Jörg Piper; **Explore the Microbial World Figure 1c:** David A. Stahl.

Chapter 22 Chapter Opener: Jason Flowers; **22.1:** Thomas D. Brock; **22.3:** Kodzo Gbewonyo; **22.4a:** Ravin Donald; **22.4b:** Thomas D. Brock; **22.5:** Thomas D. Brock; **22.6:** Kenneth Hurst Williams & Derek R. Lovley; **22.7a, b:** U.S. Environmental Protection Agency Headquarters; **22.7c:** Bassam Lahoud/Lebanese American University; **22.8:** Thomas D. Brock; **22.9:** Designlements/Fotolia; **22.14a:** Dr. Helmut Brandl/University of Zurich, Switzerland;

22.14d: Shutterstock/Mariyana Misaleva; **22.15a:** John M. Martinko; **22.15c:** Michael T. Madigan; **22.16:** Michael T. Madigan; **22.18:** Richard F. Unz/Penn State University Archives; **22.21b:** Royal Haskoning DHV, www.Nereda.net; **22.21c:** Mari Winkler; **22.22a:** Thomas D. Brock; **22.23a:** Louisville Water Company; **22.25:** Don Howard/Centers for Disease Control and Prevention; **22.26:** Norman R. Pace; **22.27c:** Shawna Johnston and Gerrit Voordouw.

Chapter 23 Chapter Opener: Shunichi Takahashi; **23.1a:** Pierre Philippe Laissue; **23.1b:** Thomas D. Brock; **23.1c:** Michael T. Madigan; **23.2a:** Pierre Philippe Laissue; **23.2b:** Thomas D. Brock; **23.4:** Michael T. Madigan; **23.5:** Michael T. Madigan; **23.6:** Viola Krukenberg, Katrin Knittel, and Gunter Wegener; **23.8:** Joe Burton; **23.9:** Ben B. Bohlool; **23.10:** Joe Burton; **23.12a:** M. D. Shakhawat Hossain; **23.12b, c:** Howard Berg, Donald Danforth Plant Science Center; **23.17:** B. Dreyfus; **23.18:** J. H. Becking/Wageningen Agricultural University, Wageningen, Netherlands; **23.20a:** Félix Fracchia; **23.20b-d:** Heike Bucking; **23.21:** Sergey Ivanov and Maria Harrison; **23.23:** S. A. Wilde, **inset:** D. J. Read/University of Sheffield, England; **23.24:** Jo Handelsman/University of Wisconsin at Madison; **23.27:** Amparo Latorre; **Explore the Microbial World Figure 1a, b:** Shee-Mei Lok and Guntur Fibriansah, **Figure 1c:** James Gathany/CDC; **23.28a:** blinkwinkel/Teigler/Alamy Stock Photo; **23.29:** Michael Poulsen and Cameron Currie; **23.30:** Nancy Moran; **23.31c:** Michael Pettigrew/Shutterstock; **23.32:** Michael Pettigrew/Shutterstock; **23.33:** Kenneth H. Nealson, University of Wisconsin; **23.34:** Margaret McFall-Ngai; **23.35a, b, d:** Margaret McFall-Ngai; **23.36a:** Dudley Foster/Woods Hole Oceanographic Institution; **23.36b:** Carl Wirsén/Woods Hole Oceanographic Institution; **23.37:** Colleen M. Cavanaugh, Harvard University; **23.38a, b:** Heidi Goodrich-Blair, Mengyi Cao, Matthew Stilwell, and Elle Kiehl Grevstad at the Biochemistry Optical Core, Biochemistry Dept. UW-Madison; **23.38c:** Sam Kyu-Kim and S. Patricia Stock; **23.39:** Kazuhiko Koike; **23.40:** Pierre Philippe Laissue; **23.41:** Michael T. Madigan; **23.44 sheep:** Gallas/Fotolia, **bird:** Bernard Swain, **horse:** Nancy L. Spear, **rabbit:** D Photo Sudbury/Shutterstock; **23.45b:** Sharisa D. Beck; **23.47:** Eric Issele/Shutterstock.

Chapter 24 Chapter Opener: Dr. Andrey Shkoporov; **24.4a:** Dwayne C. Savage and R. V. H. Blumershteyn; **24.4b:** Dwayne C. Savage; **24.8:** Ryan Hunter, Batbileg Bor, Xuesong He and Jeffrey McLean; **24.10:** Jessica Mark Welch and Gary Borisy; **24.13b:** John Durham/Science Source; **24.17:** Amina Bouslimani & Pieter Dorrestein; **24.18c:** Jeremy J. Barr; **24.26:** Trygve Lie, School of Dentistry, University of Bergen; **24.29:** Deborah O. Jung and John Martinko.

Chapter 25 Chapter Opener: Joshua Jenkins; **25.2a:** USDA Agricultural Research Service; **25.3a:** Larry Stauffer/Oregon State Public Health Laboratory/CDC; **25.3b:** CDC/PHIL; **25.3c:** J. William Costerton/Montana State University; **25.4a:** M. Miller/CDC; **25.4b:** CDC/PHIL; **25.4c:** Richard Facklam/CDC; **25.5:** CDC/PHIL; **25.7a, b:** C. Lai, Max A. Listgarten, and B. Rosan; **25.7c:** Richard Facklam/CDC; **25.7d:** Isaac L. Schechmeister and John J. Bozzola/Southern Illinois University at Carbondale; **25.8:** Jessica Mark Welch and Gary Borisy; **25.9:** Janice Haney Carr/CDC; **25.13:** CDC/PHIL; **25.16:** Zang, R. G., Scott, D. L., Westbrook, M.L., Nance, S., Spangler, B.D., Shipley, G.G., Westbrook, E.M. Journal: (1995) *J.Mol. Biol.* 251: 563-573; **25.17a:** Thomas D. Brock; **25.17b:** Leon J. Le Beau/University of Illinois at Chicago; **25.18 left:** 2-methyl-2, 4-pentanediol induces spontaneous assembly of staphylococcal alpha-hemolysin into heptameric pore structure. Tanaka, Y. Hirano, N., Kaneko, J., Kamio, Y., Yao, M., Tanaka, I. (2011) *Protein Sci.* 20: 448-456; **right:** Janice Haney Carr/CDC; **25.19:** Janice Haney Carr/CDC; **25.20:** Arthur O. Tzianabos and R.D. Millham.

Chapter 26 Chapter Opener: Florian Ermini/Cortexyme; **26.3:** Dr. Deepak Kumar, Vijaya Kumar, and

Dr. Robert Moir; **Table 26.2a:** John M. Martinko and Michael T. Madigan; **26.7b:** NIAID (CDC/PHIL); **Explore the Microbial World Figure 1:** U.S. National Oceanic and Atmospheric Administration; **26.10:** J. G. Hirsch; **26.12a:** Centers for Disease Control and Prevention; **26.12b:** James V. Little; **26.15b:** Michelle Dunstone and Bradley Spicer, Centre of Excellence for Advanced Molecular Imaging.

Chapter 27 Chapter Opener: NIAID/NIH; **27.5 left to right:** CDC/PHIL, US WPA/Library of Congress, D. Jordan, M. A./CDC, Edward J. Wozniak, D.V.M., PH.D./CDC; **27.8b:** Richard J. Feldmann, National Institutes of Health; **27.13d:** Don C. Wiley, Howard Hughes Medical Institute; **27.13e:** Aileen C. M. Young, Albert Einstein College of Medicine, Bronx, New York; **27.13f:** Jerry H. Brown; **27.16:** Boensch, B./Arco Images GmbH/Alamy Stock Photo; **27.22b:** Alex Ritter, Jennifer Lippincott Schwartz, and Gillian Griffiths, National Institutes of Health; **27.23b:** Lennart Nilsson, Albert Bonniers Forlag AB.

Chapter 28 Chapter Opener: Oliver Meckes/Science Source; **28.2:** Edward J. Wozniak/D.V.M./PH.D./CDC; **28.3:** CDC/PHIL; **28.4:** CDC/PHIL; **28.5:** CDC/PHIL; **28.7:** NIAID (CDC/PHIL); **28.8:** Amanda Mills/CDC; **28.15:** Biophoto Associates/Science Source; **28.16:** Dr. P. Marazzi/Science Source.

Chapter 29 Chapter Opener: National Institute of Allergy and Infectious Diseases (NIAID); **29.1:** CDC/PHIL; **29.2:** USAMRIID; **Table 29.3:** Janice Haney Carr/CDC, Peta Wardell/CDC, Erskine Palmer/CDC, A. Harrison/CDC, Frederick Murphy/CDC, Charles D. Humphrey/CDC; **Explore the Microbial World Figure 1a:** Alberto Lerner/CHROMagar, **Figure 1b:** NIAID (CDC/PHIL); **29.6a:** Norman Jacobs/CDC; **29.6b:** CDC/PHIL; **29.7a, b:** Dr. Todd Parker/CDC; **29.7c:** John M. Martinko and Cheryl L. Broadie; **29.8:** Matthew Sattley; **29.9:** Matthew Sattley; **29.10:** Leon J. Le Beau; **29.11a:** Leon J. Le Beau; **29.11b, c:** Matthew Sattley; **29.11g:** Richard Facklam/CDC; **29.14:** C. Weibull, W. D. Bickel, W. T. Hashius, K. C. Milner, and E. Ribi; **29.15a:** Norman L. Morris; **29.16:** Matthew Sattley; **29.18a:** Wellcome Research Laboratories; **29.18b:** William B. Cherry/CDC; **29.19a:** P. M. Feorino/CDC; **29.19b:** William Kaplan/CDC; **29.19c:** Govinda S. Visvesvara/CDC; **29.21a:** Matthew Sattley; **29.22b:** Victor Tsang/CDC; **29.24b:** Matthew Sattley.

Chapter 30 Chapter Opener: Jeniel E. Nett; **30.5 left:** James Gathany/CDC, **right:** CDC/PHIL; **30.6 left:** Janice Haney Carr/CDC, **right:** NIAID (CDC/PHIL); **30.8 left:** CDC/PHIL, **right:** Jim Goodson/CDC; **30.12a:** James Gathany and CDC/Melissa Dankel; **30.12b:** Gilda Jones/CDC; **30.17:** CDC/PHIL; **30.18a, d:** CDC/PHIL; **30.18b:** Larry Stauffer, Oregon State Public Health Laboratory, and CDC/PHIL; **30.18c:** Archil Navdarashvili, Georgia (Republic)/CDC.

Chapter 31 Chapter Opener: Brinkmann, Max Planck Institute for Infection Biology; **31.1:** Thomas D. Brock; **31.3a:** Eye of Science/Science Source; **31.3b:** CDC/PHIL; **31.4:** Michael T. Madigan; **31.5:** CDC/PHIL; **31.6:** Franklin H. Top; **31.7:** Dr. Thomas F. Sellers/CDC; **31.8:** Michael T. Madigan; **31.9:** Franklin H. Top; **31.10:** Dr. M.A. Ansary/Science Source; **31.11:** Isaac L. Schechmeister; **31.12:** CDC/PHIL; **31.13a:** CDC/PHIL; **31.13b:** Franklin H. Top; **31.14:** J. H. Carr/CDC; **31.15a:** Dr. Edwin P. Ewing Jr./CDC; **31.15b:** CDC/PHIL; **31.16a:** R. W. Smithwick/CDC; **31.16b, c:** Aaron Friedman; **31.17a:** Jorge Adorno/Reuters; **31.17b:** CDC/PHIL; **31.18:** CDC/PHIL; **31.19a:** C. Goldsmith/CDC; **31.19b:** Centers for Disease Control and Prevention; **31.19c:** CDC/PHIL; **31.20:** CDC/PHIL; **31.21:** Centers for Disease Control and Prevention; **31.22:** A. D. Langmuir/CDC; **31.23a:** Biophoto Associates/Science Source; **31.23b:** David A. J. Tyrrell; **31.24:** E. L. Palmer, M. L. Martin, and F. Murphy/CDC; **31.25:** Irene T. Schulze; **31.28:** CDC/PHIL, M. J. Arduino and J. H. Carr/CDC; **31.29:** Gregory Moran/CDC; **31.30:** Michael T. Madigan; **31.31:** Juergen Berger/Science Source; **31.33a:** Eye of Science/Science Source; **31.33b:** CDC/PHIL; **31.34a:** Cynthia Goldsmith/CDC;

31.34b: CDC/PHIL; **31.36a:** Joe Miller/CDC; **31.36b:** Morris D. Cooper; **31.37a:** H. Russell/CDC; **31.37b, c:** CDC/PHIL; **31.38a:** Centers for Disease Control and Prevention; **31.38b:** Sidney Olansky; **31.38c:** Robert Sumpter/CDC; **31.39:** Dr. Peter Perine/CDC; **31.40:** Morris D. Cooper; **31.41a:** Gordon A. Tuffli, MD; **31.41b:** K. L. Hermann/CDC; **31.42a:** N. J. Flumara and G. Hart/CDC; **31.42b:** Susan Lindsley/CDC; **31.46:** CDC/PHIL; **31.47a:** CDC/PHIL; **31.47b:** S. Krans/CDC; **31.48a:** M. Metcalfe and T. Hodge/CDC.

Chapter 32 Chapter Opener: National Institute of Allergy and Infectious Diseases (NIAID); **32.2a:** Dr. Fred Murphy/CDC; **32.2b:** Mekonnen Fekadu/CDC; **32.3a:** Cynthia Goldsmith and Luanne Elliot/CDC; **32.3b:** Natalie Dolan/CDC; **32.4a:** James Gathany/CDC; **32.4b:** CDC/PHIL; **32.6a:** Willy Burgdorfer, M.D.; **32.6b:** CDC/PHIL; **32.6c:** Willy Burgdorfer, MD; **32.6d:** Kenneth E. Greer/University of Virginia School of Medicine; **32.7a:** D. H. Walker/CDC; **32.7b:** National Institute of Allergy and Infectious Diseases (NIAID); **32.8a:** National Institute of Allergy and Infectious Diseases (NIAID); **32.8b:** Janice Haney Carr/CDC; **32.9a:** Pfizer Central Research; **32.9b:** James Gathany/CDC; **32.10:** Pfizer Central Research; **32.12a:** James Gathany/CDC; **32.12b:** CDC/PHIL; **32.12c:** Frederick Murphy/CDC; **32.13:** Cynthia Goldsmith/CDC; **32.14a:** W. Brogdon, J. Gathany/CDC; **32.14b:** Cynthia Goldsmith/CDC; **32.15:** CDC/PHIL; **32.17a:** Larry Stauffer/CDC; **32.17b:** T. Parker/CDC; **32.18a:** CDC/WHO; **32.18b:** Larry Stauffer/CDC; **32.19a:** CDC/PHIL; **32.19b:** Christina Nelson, MD, MPH/CDC; **32.21a:** Larry Stauffer/CDC; **32.21b:** Janice Haney Carr/CDC; **32.22a:** Larry Stauffer/CDC; **32.22b-d:** CDC/PHIL; **32.23:** CDC/PHIL; **32.24:** CDC/PHIL; **32.24c:** Biophoto Associates/Science Source.

Chapter 33 Chapter Opener: Michael T. Madigan; **33.1a:** Thomas D. Brock; **33.1b:** U.S. Environmental Protection Agency Headquarters; **33.1c:** Jade ThaiCatwalk/Shutterstock; **33.2 clockwise from top:** Kimberley Seed, Tufts University School of Medicine, Centers for Disease Control and Prevention, James Cavallini/Science Source, Centers for Disease Control and Prevention, Mark L. Tamplin, Juergen Berger/Science Source; **33.3a, b:** CDC/PHIL; **33.3c:** Janice Haney Carr/CDC; **33.3d:** Jim Feeley/CDC; **33.4:** CDC/PHIL; **33.5:** Thomas D. Brock; **33.6:** John M. Martinko and Cheryl Broadie; **33.7:** Seward Laboratory Systems Inc.; **33.8a:** CDC/PHIL; **33.8b:** Janice Haney Carr/CDC; **33.9:** CDC/PHIL; **33.10a:** Eric Grafman/CDC; **33.10b, c:** James Gathany/CDC; **33.10d:** Michael T. Madigan; **33.11:** CDC/PHIL; **33.12a:** CDC/PHIL; **33.12b:** Janice Haney Carr/CDC; **33.12c, d:** CDC/PHIL; **33.13a, b:** CDC/PHIL; **33.13c:** Mediscan/Alamy Stock Photo; **33.14a:** Michael T. Madigan; **33.14b:** Elizabeth White/CDC; **33.15b:** Dr. Pascale Cossart, Institut Pasteur, Paris; **33.16:** CDC/PHIL; **33.17:** CDC/PHIL.

Chapter 34 Chapter Opener: Dr. Visvesvara/CDC; **34.1a:** L. Haley/CDC; **34.1b:** A. A. Padhye/CDC; **34.1c:** M. Jalbert/L. Kaufman/CDC; **34.1d, e:** L. Ajello/CDC; **34.1f:** L. K. Georg/CDC; **34.2a:** CDC/PHIL; **34.3a:** Gordon C. Sauer, MD; **34.3b, c:** CDC/PHIL; **34.4a:** Gordon C. Sauer, MD; **34.4b:** L. K. Georg/CDC; **34.5a:** M. Hicklin/CDC; **34.5b:** L. K. Georg/CDC; **34.5c:** E. P. Ewing, Jr./CDC; **34.5d:** M. Hicklin/CDC; **34.5e:** M. Castro/L.K. Georg/CDC; **34.5f:** CDC/PHIL; **34.6:** Katherine Ralston and David Zemo; **34.7a:** M. Melvin/CDC; **34.7b:** L. L. A. Moore, Jr./CDC; **34.8a:** G.S. Visvesvara/CDC; **34.8b:** Stanley L. Erlandsen; **34.8c:** Dennis E. Feely; **34.9a:** Steve J. Upton; **34.9b:** CDC/PHIL; **34.10:** CDC/PHIL; **34.11:** Edwin P. Ewing/CDC; **34.12:** Jim Gathany/CDC; **34.13a:** Steven Glenn/CDC; **34.13b:** M. Melvin/CDC; **34.14a:** F. Collins/J. Gathany/CDC; **34.14b:** M. Melvin/CDC; **34.14c:** D. S. Martin/CDC; **34.15a:** Scott Camazine/Alamy Stock Photo; **34.15b:** Myron G. Schultz/CDC; **34.15c:** WHO (CDC/PHIL); **34.15d:** M. Melvin/CDC; **34.16a:** S. Maddison/CDC; **34.16b:** CDC/PHIL; **34.16c:** A. J. Sulzer/CDC; **34.16d:** CDC/PHIL; **34.17:** CDC/PHIL; **34.18:** CDC/PHIL.

Glossary Terms

NOTE: Page numbers indicate where the term is defined in a Chapter Glossary. A few entries with more than one page number are used in more than one sense. Comprehensive glossary available at **Mastering Microbiology®**.

- ABC transport system** (Ch 2, p. 109)
Acetogenesis (Ch 14, p. 512)
Acid-fastness (Ch 16, p. 591)
Acid mine drainage (Ch 22, p. 779)
Acidophile (Ch 4, p. 182)
Acridine orange (Ch 19, p. 685)
Actinomyces (Ch 16, p. 591)
Activation energy (Ch 3, p. 142)
Activator protein (Ch 7, p. 268)
Acute infection (Ch 30, p. 985)
Adaptive immunity (Ch 26, p. 890)
Adherence (Ch 25, p. 867)
Adhesins (Ch 25, p. 867)
Aerobe (Ch 4, p. 182)
Aerobic anoxygenic phototroph (Ch 15, p. 554)
Aerotolerant anaerobe (Ch 4, p. 182)
Agglutination (Ch 29, p. 964)
Algae (Ch 18, p. 647)
Alkaliphile (Ch 4, p. 182)
Allele (Ch 13, p. 458)
Allergen (Ch 28, p. 942)
Allosteric protein (Ch 7, p. 268)
Amino acid (Ch 6, p. 234)
Aminoacyl-tRNA synthetase (Ch 6, p. 234)
Aminoglycoside (Ch 28, p. 942)
Anabolic reactions (anabolism) (Ch 3, p. 142)
Anaerobe (Ch 4, p. 182)
Anaerobic respiration (Ch 3, p. 142), (Ch 14, p. 512)
Anaerobic treatment (Ch 22, p. 779)
Anammox (Ch 14, p. 512)
Anoxygenic photosynthesis (Ch 14, p. 512)
Antenna pigments (Ch 14, p. 512)
Antibiotic (Ch 8, p. 296), (Ch 28, p. 942)
Antibody (Ch 26, p. 890)
Antibody-dependent cell-mediated cytotoxicity (ADCC) (Ch 26, p. 890)
Anticodon (Ch 6, p. 234)
Antigen (Ch 26, p. 890), (Ch 27, p. 918)
Antigenic drift (Ch 31, p. 1018)
Antigenic shift (Ch 31, p. 1018)
Antigen-presenting cell (APC) (Ch 26, p. 890)
Antimicrobial agent (Ch 4, p. 182)
Antimicrobial drug resistance (Ch 28, p. 942)
Antiparallel (Ch 6, p. 234)
Antiseptic (germicide) (Ch 4, p. 182)
Arbuscule (Ch 23, p. 818)
Archaea (Ch 13, p. 458)
Archaeum (Ch 2, p. 109)
Aseptic technique (Ch 1, p. 73), (Ch 4, p. 182)
Asgard Archaea (Ch 17, p. 619)
ATP (adenosine triphosphate) (Ch 3, p. 142)
ATPase (ATP synthase) (Ch 3, p. 142)
Attenuate, attenuation (Ch 7, p. 268), (Ch 12, p. 427), (Ch 25, p. 867)
Autoantibody (Ch 28, p. 942)
Autoclave (Ch 4, p. 182)
Autoimmunity (Ch 28, p. 942)
Autoinducer (Ch 7, p. 268)
Autoinduction (Ch 23, p. 818)
Autotroph (Ch 3, p. 142), (Ch 14, p. 512)
Auxiliary metabolic genes (AMGs) (Ch 20, p. 728)
Auxotroph (Ch 9, p. 327)
Average nucleotide identity (ANI) (Ch 13, p. 458)
B cell (Ch 26, p. 890)
B cell receptor (BCR) (Ch 26, p. 890), (Ch 27, p. 918)
Bacteremia (Ch 25, p. 867)
Bacteria (Ch 13, p. 458)
Bacterial artificial chromosome (BAC) (Ch 12, p. 427)
Bactericidal agent (Ch 4, p. 182)
Bacteriochlorophyll (Ch 14, p. 512)
Bacteriocin (Ch 6, p. 234)
Bacteriocyte (Ch 23, p. 818)
Bacteriome (Ch 23, p. 818)
Bacteriophage (Ch 5, p. 200)
Bacteriorhodopsin (Ch 17, p. 619)
Bacteriostatic agent (Ch 4, p. 182)
Bacteroid (Ch 23, p. 818)
Banded iron formation (Ch 13, p. 458)
Basal body (Ch 2, p. 109)
Basic reproduction number (R_0) (Ch 30, p. 985)

Nitrogenase (Ch 3, p. 143)
Nitrogen fixation (Ch 3, p. 143)
Nod factors (Ch 23, p. 818)
Noncoding RNA (ncRNA)
 (Ch 7, p. 268)
Nonnucleoside reverse transcriptase inhibitor (Ch 28, p. 942),
 (Ch 31, p. 1018)
Nonperishable foods (Ch 33, p. 1058)
Nonsense codon (Ch 6, p. 235)
Nonsense mutation (Ch 9, p. 327)
Normal microbiota (Ch 24, p. 849)
Northern blot (Ch 12, p. 427)
Nucleic acid probe (Ch 10, p. 360),
 (Ch 12, p. 427), (Ch 19, p. 686)
Nucleocapsid (Ch 5, p. 200)
Nucleoid (Ch 1, p. 73)
Nucleomorphs (Ch 18, p. 647)
Nucleoside (Ch 6, p. 235)
Nucleoside reverse transcriptase inhibitor (NRTI) (Ch 28, p. 942),
 (Ch 31, p. 1018)
Nucleotide (Ch 6, p. 235)
Nucleus (Ch 1, p. 73), (Ch 2, p. 110)
Obligate anaerobe (Ch 4, p. 183)
Oligotroph (Ch 20, p. 728)
Oligotrophic (Ch 16, p. 591)
Open reading frame (ORF)
 (Ch 6, p. 235), (Ch 10, p. 360)
Operon (Ch 6, p. 235), (Ch 7, p. 268)
Operon fusion (Ch 12, p. 427)
Opportunistic pathogen
 (Ch 25, p. 867), (Ch 31, p. 1018)
Opsonization (Ch 26, p. 891)
Organelle (Ch 1, p. 73)
Orthologs (Ch 13, p. 458)
Osmophile (Ch 4, p. 183)
Outbreak (Ch 30, p. 985)
Outer membrane (Ch 2, p. 110)
Overlapping genes (Ch 11, p. 389)
Oxidative phosphorylation
 (Ch 3, p. 143)
Oxygenase (Ch 14, p. 513)
Oxygen minimum zone (OMZ)
 (Ch 20, p. 728)
Oxygenic photosynthesis
 (Ch 14, p. 513)
Pandemic (Ch 30, p. 985)
Pan genome (Ch 13, p. 458)
Paralogs (Ch 13, p. 458)
Parasitism (Ch 23, p. 818)
Pasteurization (Ch 4, p. 183),
 (Ch 33, p. 1058)
Pathogen (Ch 1, p. 73),
 (Ch 25, p. 867)
Pathogen-associated molecular pattern (PAMP) (Ch 26, p. 891)
Pathogenicity island (Ch 13, p. 458),
 (Ch 25, p. 867)
Pathway engineering (Ch 12, p. 427)
Pattern recognition receptor (PRR)
 (Ch 26, p. 891)
Pentose phosphate pathway
 (Ch 3, p. 143)
Peptide bond (Ch 6, p. 235)
Peptidoglycan (Ch 2, p. 110)
Periplasm (Ch 2, p. 110)
Perishable foods (Ch 33, p. 1058)
Peritrichous flagellation
 (Ch 2, p. 110)
Persistence (Ch 8, p. 296)
Pertussis (whooping cough)
 (Ch 31, p. 1018)
pH (Ch 4, p. 183)
Phagocyte (Ch 26, p. 891)
Phagocytosis (Ch 18, p. 647),
 (Ch 26, p. 891)
Phagosome (Ch 26, p. 891)
Phenotype (Ch 9, p. 327),
 (Ch 13, p. 458)
Phosphodiester bond (Ch 6, p. 235)
Photophosphorylation (Ch 3, p. 143)
Photosynthesis (Ch 14, p. 513)
Photosynthetic reaction center
 (Ch 3, p. 143)
Phototaxis (Ch 2, p. 110)
Phototroph (Ch 3, p. 143),
 (Ch 14, p. 513)
Phycobilins (Ch 15, p. 554)
Phycobiliprotein (Ch 14, p. 513)
Phycobilisome (Ch 14, p. 513)
Phylogenetic diversity
 (Ch 15, p. 554)
Phylogenetic tree (Ch 1, p. 73),
 (Ch 13, p. 459)
Phylogeny (Ch 1, p. 73),
 (Ch 13, p. 459)
Phylotype (Ch 19, p. 686)
Phylum (Ch 13, p. 459)
Phytanyl (Ch 17, p. 620)
Piezophile (Ch 20, p. 728)
Piezotolerant (Ch 20, p. 728)
Pili (Ch 2, p. 110)
Plague (Ch 32, p. 1036)
Plaque (Ch 5, p. 200)
Plasma (Ch 26, p. 891)
Plasma cell (Ch 26, p. 891)
Plasmid (Ch 1, p. 73), (Ch 6, p. 235)
Plate count (Ch 4, p. 183)
Point mutation (Ch 9, p. 327)
Point-of-care diagnostics
 (Ch 29, p. 964)
Polar flagellation (Ch 2, p. 110)
Poly-β-hydroxybutyric acid (PHB)
 (Ch 2, p. 110)
Polygeny (Ch 27, p. 918)
Polymerase chain reaction (PCR)
 (Ch 12, p. 427)
Polymorphism (Ch 27, p. 918)
Polynucleotide (Ch 6, p. 235)
Polypeptide (Ch 6, p. 235)
Polyprotein (Ch 11, p. 389)
Polyvalent vaccine (Ch 12, p. 427)
Population (Ch 20, p. 728)
Positive selection (Ch 27, p. 918)
Positive strand (Ch 11, p. 389)
Potable (Ch 22, p. 779),
 (Ch 33, p. 1058)
Prebiotic (Ch 24, p. 849)
Precipitation (Ch 29, p. 964)
Prevalence (Ch 30, p. 985)
Primary amebic meningoencephalitis
 (Ch 34, p. 1073)
Primary disinfection (Ch 22, p. 779)
Primary endosymbiosis
 (Ch 18, p. 647)
Primary immune response
 (Ch 27, p. 918)
Primary lymphoid organ
 (Ch 26, p. 891)
Primary producer (Ch 20, p. 728)
Primary structure (Ch 6, p. 235)
Primary transcript (Ch 6, p. 235)
Primary wastewater treatment
 (Ch 22, p. 779)
Primase (Ch 6, p. 235)
Primer (Ch 6, p. 235)
Prion (Ch 11, p. 389)
Probiotic (Ch 24, p. 849)
Prochlorophyte (Ch 15, p. 554),
 (Ch 20, p. 728)
Prokaryotic (Ch 1, p. 73)
Promoter (Ch 6, p. 235)
Prophage (Ch 5, p. 200)
Propionic acid bacteria
 (Ch 16, p. 591)
Prosthecae (Ch 15, p. 554)
Protease inhibitor (Ch 28, p. 942),
 (Ch 31, p. 1018)
Protein (Ch 6, p. 235)
Protein fusion (Ch 12, p. 427)
Proteobacteria (Ch 16, p. 591)
Proteome (Ch 10, p. 360)
Proteomics (Ch 10, p. 360)
Proteorhodopsin (Ch 20, p. 728)
Protist (Ch 18, p. 647)
Proton motive force (pmf)
 (Ch 3, p. 143)
Phylotype (Ch 19, p. 686)
Provirus (Ch 5, p. 200)
Pseudomonad (Ch 16, p. 591)
Psychrophile (Ch 4, p. 183)
Psychrotolerant (Ch 4, p. 183)
Public health (Ch 30, p. 985)
Pure culture (Ch 1, p. 73)
Purine (Ch 6, p. 235)
Purple nonsulfur bacteria
 (Ch 15, p. 554)
Purple sulfur bacteria (Ch 15, p. 554)
Pyrimidine (Ch 6, p. 235)
Pyrite (Ch 22, p. 779)
Quarantine (Ch 30, p. 985)
Quaternary structure (Ch 6, p. 235)
Quinolone (Ch 28, p. 942)
Quorum sensing (Ch 7, p. 268)
Rabies (Ch 32, p. 1036)
Radiative forcing (Ch 21, p. 753)
Raw water (Ch 22, p. 779)
Reaction center (Ch 14, p. 513)
Realized niche (Ch 19, p. 686)
Recombinant DNA (Ch 12, p. 427)
Recombination (Ch 9, p. 327),
 (Ch 13, p. 459)
Redox balance (Ch 14, p. 513)

- Redox reaction** (Ch 3, p. 143)
Reducing power (Ch 3, p. 143), (Ch 14, p. 513)
Reduction potential (E_0') (Ch 3, p. 143)
Reductive acetyl-CoA pathway (Ch 14, p. 513)
Reductive dechlorination (Ch 14, p. 513), (Ch 22, p. 779)
Reemerging disease (Ch 30, p. 985)
Regulatory nucleotide (Ch 7, p. 268)
Regulon (Ch 7, p. 268)
Replication (Ch 6, p. 235)
Replication fork (Ch 6, p. 235)
Replicative form (Ch 11, p. 389)
Replisome (Ch 6, p. 235)
Reporter gene (Ch 8, p. 296), (Ch 12, p. 427)
Repressor protein (Ch 7, p. 269)
Reservoir (Ch 30, p. 985)
Resolution (Ch 1, p. 73)
Respiration (Ch 3, p. 143), (Ch 14, p. 513)
Response regulator protein (Ch 7, p. 269)
Restriction enzyme (Ch 12, p. 427)
Retrovirus (Ch 5, p. 200), (Ch 11, p. 389)
Reverse citric acid cycle (Ch 14, p. 513)
Reverse DNA gyrase (Ch 17, p. 620)
Reverse electron transport (Ch 14, p. 513)
Reverse transcriptase (Ch 11, p. 389)
Reverse transcription (Ch 11, p. 389)
Reversion (Ch 9, p. 327)
Rheumatic fever (Ch 31, p. 1018)
Rhizosphere (Ch 20, p. 728)
Ribosomal RNA (rRNA) (Ch 1, p. 73), (Ch 6, p. 235), (Ch 13, p. 459)
Ribosome (Ch 1, p. 73), (Ch 6, p. 235)
Riboswitch (Ch 7, p. 269)
Ribulose monophosphate pathway (Ch 14, p. 513)
Rickettsias (Ch 32, p. 1036)
RNA (ribonucleic acid) (Ch 6, p. 235)
RNA polymerase (Ch 6, p. 235)
RNA processing (Ch 6, p. 235)
RNA replicase (Ch 11, p. 389)
Rolling circle replication (Ch 9, p. 327), (Ch 11, p. 389)
Root nodule (Ch 23, p. 818)
RuBisCO (Ch 3, p. 143), (Ch 14, p. 513)
Rumen (Ch 23, p. 818)
Salmonellosis (Ch 33, p. 1058)
Sanitizer (Ch 4, p. 183)
Scarlet fever (Ch 31, p. 1018)
Schistosomiasis (Ch 34, p. 1073)
Screening (Ch 9, p. 327)
Secondary disinfection (Ch 22, p. 779)
Secondary endosymbiosis (Ch 18, p. 647)
Secondary fermentation (Ch 14, p. 513)
Secondary immune response (Ch 27, p. 918)
Secondary lymphoid organ (Ch 26, p. 891)
Secondary structure (Ch 6, p. 235)
Secondary wastewater treatment (Ch 22, p. 779)
Sediment (Ch 22, p. 779)
Selection (Ch 9, p. 327)
Selective media (Ch 29, p. 964)
Selective toxicity (Ch 28, p. 942)
Semiconservative replication (Ch 6, p. 235)
Semiperishable foods (Ch 33, p. 1058)
Sensitivity (Ch 29, p. 964)
Sensor kinase protein (Ch 7, p. 269)
Septicemia (Ch 25, p. 867)
Sequence alignment (Ch 13, p. 459)
Sequencing (Ch 10, p. 360)
Serine pathway (Ch 14, p. 513)
Serology (Ch 29, p. 964)
Serum (Ch 26, p. 891)
Sewage (Ch 22, p. 779)
Sexually transmitted infection (STI) (Ch 31, p. 1018)
Short-chain fatty acids (SCFAs) (Ch 24, p. 849)
Shuttle vector (Ch 12, p. 427)
Signal sequence (Ch 6, p. 235)
Signal transduction (Ch 7, p. 269)
Silent mutation (Ch 9, p. 327)
Simple transport system (Ch 2, p. 110)
Site-directed mutagenesis (Ch 12, p. 427)
16S rRNA (Ch 13, p. 459)
S-layer (Ch 2, p. 110)
Slime mold (Ch 18, p. 647)
Solfatara (Ch 17, p. 620)
Somatic hypermutation (Ch 27, p. 918)
SOS repair system (Ch 9, p. 327)
Southern blot (Ch 12, p. 427)
Species (Ch 13, p. 459)
Species abundance (Ch 20, p. 728)
Species richness (Ch 20, p. 728)
Specificity (Ch 26, p. 891), (Ch 27, p. 918), (Ch 29, p. 964)
Spirilla (singular, spirillum) (Ch 15, p. 554)
Spirochete (Ch 15, p. 554)
Spliceosome (Ch 6, p. 235)
Spontaneous generation (Ch 1, p. 73)
Spontaneous mutation (Ch 9, p. 327)
Spotted fever rickettsiosis (SFR) (Ch 32, p. 1036)
SSU rRNA (Ch 13, p. 459)
Stable isotope probing (SIP) (Ch 19, p. 686)
Start codon (Ch 6, p. 235)
Stationary phase (Ch 4, p. 183)
Sterilant (Ch 4, p. 183)
Sterile (Ch 1, p. 73)
Sterilization (Ch 4, p. 183)
Stickland reaction (Ch 14, p. 513)
Stop codon (Ch 6, p. 235)
Stratified water column (Ch 20, p. 728)
Stringent response (Ch 7, p. 269)
Stroma (Ch 2, p. 110)
Stromatolite (Ch 13, p. 459)
Subcutaneous mycoses (Ch 34, p. 1073)
Substrate-level phosphorylation (Ch 3, p. 143)
Subunit vaccine (Ch 12, p. 427)
Sulfa drugs (Ch 28, p. 942)
Superantigen (Ch 28, p. 942)
Superficial mycoses (Ch 34, p. 1073)
Super-resolution microscopy (Ch 8, p. 296)
Suspended solid (Ch 22, p. 779)
Symbiosis (Ch 23, p. 818)
Synbiotic (Ch 24, p. 849)
Synthetic biology (Ch 12, p. 427)
Syntrophy (Ch 14, p. 513), (Ch 21, p. 753)
Systematics (Ch 13, p. 459)
Systemic mycoses (Ch 34, p. 1073)
Systems biology (Ch 10, p. 360)
TACK superphylum (Ch 17, p. 620)
Taxonomy (Ch 13, p. 459)
T cell (Ch 26, p. 891)
T cell receptor (TCR) (Ch 26, p. 891), (Ch 27, p. 918)
T-cytotoxic (Tc) cell (Ch 27, p. 918)
T-DNA (Ch 12, p. 427)
Teichoic acid (Ch 2, p. 110)
Temperate virus (Ch 5, p. 200)
Termination (Ch 6, p. 235)
Tertiary structure (Ch 6, p. 235)
Tertiary wastewater treatment (Ch 22, p. 779)
Tetanus (Ch 32, p. 1036)
Tetracycline (Ch 28, p. 942)
Thaumarchaeota (Ch 17, p. 620)
T-helper (Th) cell (Ch 27, p. 918)
Thermophile (Ch 4, p. 183)
Thermosome (Ch 17, p. 620)
Thylakoids (Ch 2, p. 110), (Ch 14, p. 513)
Ti plasmid (Ch 12, p. 427), (Ch 23, p. 818)
Titer (Ch 5, p. 200), (Ch 29, p. 964)
Tolerance (Ch 27, p. 918)
Toll-like receptor (TLR) (Ch 26, p. 891)
Toxicity (Ch 25, p. 867)
Toxic shock syndrome (TSS) (Ch 31, p. 1018)
Toxin-antitoxin (TA) module (Ch 8, p. 296)
Transcription (Ch 1, p. 73), (Ch 6, p. 235)
Transcription factor (Ch 7, p. 269)
Transcriptome (Ch 10, p. 360)
Transduction (Ch 9, p. 327)
Transfer RNA (tRNA) (Ch 6, p. 235)
Transformation (Ch 9, p. 327)
Transgenic organism (Ch 12, p. 427)
Transition (Ch 9, p. 327)
Translation (Ch 1, p. 73), (Ch 6, p. 235)
Translatome (Ch 10, p. 360)
Transposable element (Ch 6, p. 235), (Ch 9, p. 327)
Transposon (Ch 9, p. 327)
Transversion (Ch 9, p. 327)
Trypanosomiasis (Ch 34, p. 1073)
Tuberculin test (Ch 31, p. 1018)
Turbidity (Ch 22, p. 779)
Twisting motility (Ch 2, p. 110)
Two-component regulatory system (Ch 7, p. 269)
Type strain (Ch 13, p. 459)
Typhus (Ch 32, p. 1036)
Universal tree of life (Ch 13, p. 459)
Untreated water (Ch 22, p. 779)
Upper respiratory tract (Ch 24, p. 849)
Vaccination (immunization) (Ch 27, p. 918), (Ch 28, p. 942)
Vaccine (Ch 28, p. 942)
Vector (Ch 12, p. 427), (Ch 30, p. 985)
Vector vaccine (Ch 12, p. 427)
Vehicle (Ch 30, p. 985)
Viable (Ch 4, p. 183)
Viable count (Ch 4, p. 183)
Viral load (Ch 31, p. 1018)
Virion (Ch 5, p. 200)
Viroid (Ch 11, p. 389)
Virome (Ch 24, p. 849)
Virulence (Ch 25, p. 867), (Ch 30, p. 985)
Virulence factors (Ch 25, p. 867)
Virulent virus (Ch 5, p. 200)
Virus (Ch 5, p. 200)
Volatile fatty acids (VFAs) (Ch 23, p. 818)
Wastewater (Ch 22, p. 779)
Water activity (Ch 4, p. 183)
Western blot (immunoblot) (Ch 29, p. 964)
West Nile fever (Ch 32, p. 1036)
Whooping cough (pertussis) (Ch 67)
Wild-type strain (Ch 9, p. 327)
Winogradsky column (Ch 19, p. 686)
Wobble (Ch 6, p. 235)
Xenobiotic (Ch 22, p. 779)
Xerophile (Ch 4, p. 183)
Yeast (Ch 18, p. 647)
Yeast artificial chromosome (YAC) (Ch 12, p. 427)
Zoonosis (Ch 30, p. 985), (Ch 32, p. 1036)

Index

NOTE: Page numbers in **boldface** indicate the location of a boldfaced term in chapter text as well as where the term is defined in a chapter glossary. Comprehensive glossary available at MasteringMicrobiology®. A *t* following a page number indicates tabular material, an *f* indicates a figure, and a *b* indicates boxed material.

A

- ABC transport system, **78**, 79*f*, 80, **109**, 672*f*
 Abequose, 84
 Abiotrophia, 827
 ABO blood type, 957*f*
 Abomasum, 812, 812*f*, 813
 Abortive infection, 323, 323*f*
 Abscess, 881
 culture of abscess material, 951
 Absorbed radiation dose, 176
 Absorption spectrum, 467, 467*f*, 468*f*, 470
 AB toxin, 860–63, 860*t*, 861*f*, 862*f*, 863*f*
Acanthamoeba, 185*f*, 188, 190*f*, 365, 681*f*, 773
Acanthamoeba castellanii, 197*f*
 Acceptor end, 222, 222*f*
 Acceptor site (A-site), 225, 226*f*, 227*f*
 Acceptor stem, 222, 222*f*
 Accessory pigment
 carotenoids, **470**, 470*f*, 471*f*, **512**
 phycobilins, 470–72, 472*f*
 Accidental hosts, 1022, 1023
Accumulibacter phosphatis, 766
 Acellular slime mold, 633
 Acetate, 503, 510*f*, 527, 532, 533, 587, 589, 598–600, 599*t*, 762, 840, 842
 anoxic decomposition, 733–34, 733*f*
 carbon and energy source, 574
 conversion to methane, 493, 493*f*, 598–600, 731, 733*f*
 fermentation product, 498*t*, 500, 500*f*, 501*f*, 502, 502*f*, 503, 503*f*, 505, 506, 506*f*, 510*f*, 563*f*, 571, 733, 733*f*, 800
 methanogenesis, 493, 493*f*
 oxidation, 115*t*, 117, 117*t*, 487, 488–90, 589, 741*f*
 rumen, 813*f*, 814, 815*t*
 sulfate-reducing bacteria, 485*f*, 487
 Acetate oxidizers, 566
 Acetic acid bacteria, 1045
 Acetoacetate decarboxylase, 672*f*
 Acetoacetyl-ACP, 140*f*
Acetobacter, 557*f*, 558*f*, 558*t*, 560, 650*t*, 1046*t*
Acetobacterium, 489, 489*f*
Acetobacterium woodii, 488, 489*f*
 Acetoclastic methanogen, 493
 Acetoclastic methanogenesis, 598–99, 599*t*
 Acetogen, 465, 546
 Acetogenesis, **488**–90, 488*f*, 489*f*, **512**, 703, 731*f*, 733*f*, 734, 734*t*
 energy conservation in, 489–90
 reductive, **465**, 488–90, 488*f*, 489*f*, **513**
 termite, 734, 735*f*, 800*f*, 801
 Acetoin, 500*f*, 568
 Acetone, 498*t*
 fermentation product, 498*t*, 500, 501*f*, 570
 Acetosyringone, 794
 Acetyl-ACP, 140*f*
 Acetylases, 938*t*
 Acetylcholine, 861–62, 861*f*, 862*f*

Archaea (continued)

- soil, phylogenetic diversity of, 700–02, 701f
- species numbers, 456
- sulfur-reducing, 533
- TACK superphylum, **607**, **620**
- transcription, 217–19, 218f
 - control of, 243–5, 244f
 - dual-acting transcriptional regulators, 244–5, 244f
 - ultra-small, 45b
- viruses, 185, 185f, 186, 363–64, 364f, 365f, 371–74, 372f, 373f
 - viral defense mechanisms, 717
 - virophere, 717
- Archaeum, **94**, 97, 98f, **109**
 - cell speed, 97
 - structure, 97, 98f
- Archaeoglobales, 593f, 602–03, 603f
- Archaeoglobus, 484, 532, 533, 533f, 597, 602–03, 609, 610f, 737f
- Archaeoglobus fulgidus, 603f
- Archaeplastida, 624, 624f, 642–5
- Arcobacter, 566f, 725f, 726
- Arc system, 246t
- Arctic amplification, 751
- Arctic warming, 750–51
- Arenaviridae, 1020t
- Arenavirus, 982t
- Arginine
 - cyanophycin, 519
 - fermentation, 501–02, 501f
 - genetic code, 224t, 333, 334t
 - mutations, 302, 302f
 - structure, 220f
 - synthesis, 138f, 240, 240f, 241, 241f
- Arginine regulon, 243
- Arginine repressor, 240, 240f, 241, 242–3
- Aridity index, 699
- Arid soils, 699–700
- ARISA, 665, 665f
- Armatimonadetes, 556f
- Aromatic amino acid, synthesis, 264, 264f
- Aromatic antibiotic, 937t
- Aromatic compounds, 734
 - fermentation, 125
- Aromatic family, synthesis, 138f
- Aromatic hydrocarbons, 508–10, 508f, 510f
 - anaerobic degradation of, 508–10, 509f, 510f
 - metabolism, 508–10, 508f, 510f
- Arsenate, 486
 - reduction, 589
- Arsenate respiration, 461f
- Arsenic, 486, 756, 756f, 764, 782
- Arsenic compound, electron acceptor, 486
- Arsenite, 486
- Artemisia annua, 416, 416f
- Artemisinin, 416, 416f, 937, 1068
- Arthritis, 569, 1001
- Arthrobacter, 567f, 573, 573f
- Arthrobacter crystallopoietes, 573f
- Arthrobacter globiformis, 573f
- Arthropod-transmitted bacterial and viral diseases, 1023–32
- Arthropod vector, 969, 970, 970t, 978, 979
- Arthrospira maxima, 518f
- Arthrospores, 161
- Articulavirales, 365
- Artificial active immunity, 897–98, 897f, 898t, 935–28
- Artificial chromosomes, 396–98, 396f, 397f, **411**, 411f
- Artificial joints, 850
- Artificial passive immunity, 897–98, 897f, 898t
- Asao, Marie, 557f
- Asci (singular, ascus), 640, 640f
- Ascidia, 808t
- Ascomycota (ascomycetes), 636f, 637, 637f, 638f, 640–1, 640f, 641f
- Ascospore, 637
- Aseptic technique, **61**, **73**, **149**–50, 149f, **182**
- Asgard Archaea, **607**–08, 608f, **619**, 704

- Asian flu (H2N2 virus), 1000
- A-site, ribosome, 225, 226f, 227f
- Asparagine, 789f
 - endospore germination, 283–84, 284f
 - genetic code, 224t
 - structure, 220, 220f
 - synthesis, 138f
- Aspartate
 - biocrust metabolome, 671, 673, 673f
 - purine synthesis, 139f
 - structure, 220f
 - synthesis, 138f, 139, 139f
- Aspartic acid
 - genetic code, 224t
 - pyrimidine biosynthesis, 139ff
- Aspergillosis, 1061t
- Aspergillus, 61, 61f, 636f, 637, 640, 774, 958, 958f, 1044t, 1046t, 1061, 1061f, 1061t
 - gut fungi, 346, 347f
- Aspergillus flavus, 1061, 1061f
- Aspergillus fumigatus, 636f
- Aspergillus nidulans, 339t
- Aspergillus niger, 176t
- Assaying antimicrobial activity, 178–79, 178f
- Assembly, genome, 332, 332f
- Assembly, viral replication, 191, 192, 192f
- Assimilative metabolism, 463–64
 - sulfate reduction, 484–85, 484f
- Assimilative reduction, 464
- Asterolampra, 629
- Asthma, 825, 839, 921
- Asticcacaulis, 549f, 549t
- Asticcacaulis biprosthecum, 549f
- Astrovirus, 1055
- Athlete's foot, 637, 1061t, 1062, 1062f
- Atmosphere
 - early Earth, 432–34
 - methane paradox, 746b, 747f
 - oxygen accumulation, 429f, 433–34
 - Atopic dermatitis, 839
 - Atopobium, 822f
- ATP, 112–113, 112f, **118**–9, **142**, 203,
 - production, use. *See also* Mitochondria
